Abstract

In this study, rock material from Laxemar, Oskarshamn, Sweden have been crushed into smaller fractions using traditional crushing with hammer and swing mill with agate mortar and by an alternative method developed by selFrag AB in Switzerland where the rock is subjected to high voltage pulse power fragmentation. Grains produced from these two crushing methods were compared with regards to:

- alteration and fragmentation of the crushed samples using an optical microscope and a Scanning Electron Microscope (SEM),
- pore size distribution calculated from N₂ adsorption analysis,
- oxygen consumption by monitoring the O₂ (g) over sterilized samples of crushed rock in deionised water using gas chromatography,
- sorption capacity of Sr²⁺ in a synthetic groundwater by determining the distribution coefficient (R_d) and the adsorption and desorption isotherms, of which the latter two suffered from experimental problems and higher uncertainties than the former methods, which data thus can be classified as being of higher quality.

The ambition of the study was to investigate which of the crushing methods that is most able to produce material representative for intact bedrock. Unfortunately, the material used for the different crushing methods differed slightly in mineralogical and chemical composition, although being sampled at close distance (m scale) and from the same rock type.

None of the crushing methods have created grains that show similar pore size distributions over the entire spectra of grain sizes. This indicates, together with SEM-observations of micro-fracture formation, that both crushing methods have led to alteration of the rock material making none of them representative for intact bedrock and implies that none of the crushing methods have produced completely unaffected grains. Even if the pore size distribution curves demonstrate that there is some variability in pore occurrence between the high-voltage crushed grain size fractions, the observed slightly greater oxygen consumption, the more angular feldspar surfaces and the higher amount of micro-fractures indicate that mechanical crushing has created larger area of reactive surfaces or higher reactivity of the surfaces. The SEM investigations showed that the high voltage crushing has affected grains less than the mechanical crushing, and also produced grains that are more similar between different size fractions. Therefore, although the general conclusion is that high voltage crushing method creates a material that is most representative for intact bedrock, although there are large uncertainties related to some of the experimental methods and to the slight difference in starting material composition.

1 Introduction

1.1 Background

The properties of the bedrock that constitutes the third barrier in the proposed storage method KBS-3 are important aspects regarding the final repository of spent nuclear fuel (HLW) in Sweden. The first barrier is a copper canister with a thickness of 5 cm and a cast iron inset and the second is a layer of bentonite clay used to protect the canister against minor movements in the bedrock, to limit the inflow of the low concentrations of corrosive agents in the groundwater and to minimize radionuclide mobilization in case of canister failure (Rosborg and Werme 2008).

1.1.1 Reducing and sorption capacity

The copper canisters holding the HLW may corrode if in contact with oxygen (O_2) -containing water. This water could be introduced via highly transmissive fractures during a future glacial period when melt water may contain a relatively high amount of dissolved oxygen, low concentration of organic matter and the groundwater flow might be enhanced (Spiessl et al. 2007, Drake et al. 2009). During the initial period after backfilling, the HLW repository will also be subjected to a period of increased dissolved oxygen, compared to the undisturbed reducing conditions of the groundwaters at the actual depth (Yang et al. 2007).

In case of canister failure, dissolved oxygen present in the groundwater may increase the mobility of several long-lived radionuclides (Rivas-Perez et al. 2003, Toulhoat 2002). Organic material is present at repository depth in concentrations enough to allow for complete oxygen reduction by microbial activity (Pedersen 2000) but it is still important to investigate the abiotic contribution to the reducing capacity in the form of reduced minerals present on fracture walls (*e.g.* chlorite) and in the rock matrix (*e.g.* biotite and pyrite) (Drake et al. 2008, Sidborn and Neretnieks 2008, Sidborn et al. 2010). Furthermore, it is important to study the sorption capacity of the bedrock to investigate its capacity to retard potential mobilized radionuclides (Toulhoat 2002).

1.1.2 Representative rock material

Because diffusion and reaction rates are slow in intact bedrock, smaller fractions of rock are generally used in laboratory experiments. Traditionally, larger pieces of bedrock are crushed mechanically using a swing mill with agate mortar or a hammer to acquire smaller fractions. However, this crushing method could create surfaces with higher reactivity because fragmentation may occur across mineral grains instead of along natural grain boundaries where the binding energy is weaker (Friedman et al. 1972). Furthermore, mechanical crushing is hypothesized to alter the surfaces of the grains through an increase in micro-cracks leading to an overestimation of the surface area, in particular for smaller fractions (André 2009). Therefore, concern has been raised regarding how representative mechanically crushed grains are for intact bedrock. selFrag AG in Switzerland has developed a new crushing method where rock samples are submerged in water and fragmented using high voltage (HV) pulsed power technology. This allows the grains to be separated along natural grain boundaries (www.selfrag.se). The hypothesis is that the HV method will create grains that are more representative for the actual bedrock, compared with the mechanical crushing method.

1.2 Aim of the study

The aim of this study was to investigate potential differences in rock material crushed by two different methods, *i.e.* mechanically crushed (M) material and rock fragmented using high voltage current (HV). The parameters studied were:

- 1) oxygen consumption,
- 2) sorption capacity and weathering tendency,
- 3) fracturing and possible alteration of grains,
- 4) pore size distribution.

These provide material-specific information that can be of use in the context of a repository for spent nuclear fuel, e.g. with regard to abiotic oxygen consumption after the operation phase (1), retardation of radionuclides by sorption (2) and matrix diffusion (implications from 4). The third parameter is mainly used to test the suitability of different crushed materials to be used in experiments to interpret the other parameters.

1.3 Limitations

The starting conditions for this study were not optimal because the original rock material (samples from the borehole KLX09C, Laxemar, Oskarshamn) used for preparation according to the two different crushing methods differed somewhat in both foliation and composition. Compensations for this were made when possible during the interpretation of the results but it would have been more favourable if the rock had been more homogeneous resulting in the same rock composition for both samples and their respective size fractions. The reason for the difference in rock composition is the heterogeneity of the rock type. Both samples are Ävrö granite, from the same borehole and sampled only two meters apart and it was therefore assumed that their composition would be very similar. Unfortunately, this was not the case, which partly may be attributed to relatively small sample volumes, due to the narrow drill core diameter and fractures that had to be avoided. A further explanation is that the rock is porphyritic, with large feldspar phenocrysts. The latter are heterogeneously distributed and have large effect on the composition if sample volumes are small.

2 Materials and experimental methods

2.1 Rock material

Two samples were taken at the beginning of 2010 from the borehole KLX09C in Laxemar, Oskarshamn. The borehole was drilled in January 2006 and the cores subsequently stored in drill core wooden boxes. The sample that was sent to Switzerland for high voltage crushing originated from 38 m while the mechanically crushed sample was taken from 40 m depth. Intact samples of the drill core from the depths of interest were also investigated.

2.2 Crushing methods

Throughout this report the abbreviations “M” and “HV” are used to denote samples crushed mechanically and through high-voltage pulse power fragmentation, respectively.

The mechanical crushing was performed by Isochron Geoconsulting, Sweden, using hammer (sample was wrapped in paper to avoid metallic iron from the hammer in the crushed material) and swing mill with agate mortar inset. Hammer was used as a first step in order to make drill core pieces small enough to fit into the agate mortar.

The high-voltage pulse power fragmentation was conducted at selFrag AG, Kerzers, Switzerland. Worth noting is that due to limited size of the sample preparation vessel at selFrag the sample was subjected to some mechanical treatment prior to the high voltage fragmentation. The process water in which the sample was submerged was degassed with N₂ gas purging to avoid oxidation, and a PTFE vessel and a special Cu-electrode were used to avoid iron contamination. The sample was treated with a pulse voltage of 110–140 kV and a frequency of 2 Hz. After treatment, the sample was sedimented and decanted, freeze dried, PUR-sieved and shipped in vacuum-sealed bags to the University of Stockholm.

Both samples (mechanically crushed and high-voltage fragmentation) were sieved by Isochron Geoconsulting, Sweden, to acquire five different size fractions; <0.25 mm, 0.25–0.5 mm, 0.5–1.0 mm, 1.0–2.0 mm and 2.0–3.0 mm. The mechanical milling and all sieving was performed during the period May–June 2010 in aerobic environment and the samples thereafter were kept in plastic jars with lids.

Samples resulting from both crushing methods were washed in ethanol-water mixtures before the redox and sorption experiments, as described below in Sections 2.6 and 2.7, in order to remove small particles and to achieve sterile conditions.

2.3 Chemical/mineral composition, element distribution and rock classification

The rock samples were sent to ALS Scandinavia AB for total extraction and quantification using ICP-QMS and ICP-AES. Materials analysed for both HV and M sample were: pieces of the intact drill cores (crushed and ground without sieving) and the 0.5–1.0 mm size fractions.

Rock classification was performed according to the IUGS (International Union of Geological Sciences) classification system. The classification was performed at Stockholm University through identification of minerals in 30 µm thin sections prepared from the drill cores (using a polarizing petrographic microscope in plane-polarized and cross-polarized light). For the analysis 1,000 points of the thin sections were identified in order to determine the mineral content of the bedrock with high certainty.

Thin sections were also prepared from the 0.5–1.0 mm and 2.0–3.0 mm size fractions.

2.4 Pore size distribution and surface area

Data from measurements of N₂ adsorption (Micromeritics ASAP 2020, Surface area and porosity analyser) were used to calculate the pore size distribution using the density functional theory (DFT). The samples are dried for 6 hours at 350°C with a vacuum set point of 10 µmHg. The equilibrium criterion for the isotherm measurements was <0.01% under 10 sec.

The DFT method allows the pore size distribution (PSD) to be determined over a relatively large range of pore diameters compared to older models. The PSD was calculated for all samples using the DFT Plus v3.00 (ASAP 2020 v1.05) software from Micromeritics for slit-shaped pores. DFT is a quantum mechanical modelling method used in physics and chemistry to investigate the electronic structure of many-body systems (cf. Ravikovitch et al. 1998). Samples from the 0.5–1.0 mm size fractions (about 11 to 15 g) were analysed in duplicates to verify/validate the results of the BET (Brunauer, Emmett, and Teller) surface area and pore size measurements. The total uncertainty in the surface area analysis is estimated to be less than 10%.

Before the experiments all samples were washed in ethanol and decanted to remove dust particles and then dried in an oven at 110°C. The measurements were performed in August and November 2010.

2.5 Sample fracturing and alteration

To verify any potential differences in fracturing and possible alteration of the samples during the two different crushing procedures, both in grain boundaries and within grains, thin sections of the drill cores and the 0.5–1.0 mm and 2.0–3.0 mm size fractions (mounted in epoxy on a glass slide and polished) were investigated using a scanning electron microscope (SEM JEOL JSM-7000F).

2.6 Redox Reactivity

The reactivity towards dissolved O₂ was tested through batch experiments. Flasks of ca 115 mL containing ca 30 g crushed rock of the 1.0–2.0 mm size fraction and 65 mL water as well as control samples with no rock material and ca 75 mL water were prepared by Microbial Analytics Sweden AB and sealed with a rubber septum (Table 2-1). All the materials and solutions (except the mineral samples) were autoclave-sterilized to prevent any microbial contribution to oxygen consumption and, hence, focus the study on the intrinsic reducing capacity of the minerals present. The mineral samples were previously sterilised by washing with a 70% ethanol aqueous solution and then rinsing with sterilised distilled water. At the beginning of the experiment each flask was injected with ca 2.6 mL air ($\approx 1.08 \cdot 10^{-4}$ mol O₂) and the O₂ concentration in the gas phase was then monitored regularly using gas chromatography (parameters listed in Table 2-2 below). Duplicate flasks of both HV and M as well as control samples without rock material were prepared. The control samples should not show any change in O₂ due to consumption and therefore these changes in oxygen are considered to represent the variations that might occur due to possible leakage of oxygen into the flasks (+), potential oxygen consumption by microbes (-) and the error range of the gas chromatograph (\pm). The estimated uncertainty of the method was $\pm 5\%$. The amount of O₂ added is well below the expected Fe(II) content of the rock samples, which should be ≈ 0.01 mol (from an Fe₂O₃ content of $\approx 6\%$, assuming that half of the iron is Fe(II), see Drake and Tullborg (2006, Section 7.5).

Table 2-1. Starting conditions for the O₂ consumption samples before and after air injection.

Sample	Rock material (g)	H ₂ O (mL)	O ₂ (ppm) before injection	O ₂ (ppm) (+1 day)
Control 1	–	75	<1,000	12,963.1
Control 2	–	74	<1,000	14,989.3
HV1	30.06	64	<1,000	14,723.6
HV2	30.03	63	<1,000	12,971.7
M1	30.07	64	<1,000	16,511.8
M2	30.04	64	<1,000	15,428.6

Table 2-2. Parameters used for the determination of oxygen concentration in the gas phase using the gas-chromatograph.

Parameter	Setup
Column	CP-PoraBOND Q 25 m × 0.32 mm and CP-Molsieve 5A 50 m × 0.53 mm (parallel)
Detector	Thermal Conductive Detector (TCD)
Carrier gas	Helium (flow: 20 mL/min)
Temperature	50°C
Injection	Split1-2

Because both the gas phase volume and the injected volume of air differed slightly between flasks there was some difference in starting concentration of O₂ between the samples (Table 2-1).

The syringe used for gas extraction from the flasks and subsequent injection into the GC was flushed with helium gas prior to each extraction of 200 µL to avoid O₂ contamination of the samples. The sterile environment in the flasks was maintained by washing all equipment in ethanol before use.

The argon gas contained in the air injected into each flask was used as a calibration of the exact volume of air initially added (ca 200 µL). Therefore, all measured oxygen peak areas were normalized against the simultaneously measured peak area of the inert Ar(g) (see Appendix A1.1).

Two measurements per flask were carried out at each sampling event. The GC parameters are listed in Table 2-2. Quantification was carried out with an external calibration curve (see Appendix, Table A1-1) and measurements were performed once per month during four months. The oxygen levels were monitored over a total time period of 217 days.

The reproducibility of the measurements of changes in the O₂ contents in the gas phase of these batch experiments was found to be ±5%.

2.7 Sorption capacity and weathering tendency

Studies of the sorption capacity were carried out using a modified method from Cui and Eriksen (1995). In the present study the radioanalytical method using ⁸⁵Sr could not be used, and Sr concentrations were analysed by ICP-OES (see 2.7.3) at Stockholm University. The sorption experiments were performed between 16 Nov. and 21 Dec. 2010 and were followed immediately by the desorption study that lasted until the end of Jan. 2011. For determination of both the *distribution coefficient* (R_d) and the adsorption/desorption *isotherms* two sets of samples were prepared in PE bottles and tubes using a synthetic groundwater (SGW) with the composition given in Table 2-3. The size fraction used was 0.5–1.0 mm. All samples were washed in ethanol before the experiment start to remove dust particles. To focus the study on the properties of the surfaces rather than the quantity of surface area, the sample weights used were determined so that the same BET surface area to SGW ratio was achieved, see Table 2-4. However, it should be noted that similar BET surface area may not *per se* give totally comparable results because BET may not correspond equally to the amount of reactive surfaces in the different samples.

Table 2-3. Composition of the synthetic groundwater (SGW). All chemicals used were of proanalytical grade.

Specie	Conc. (mM)
Na ⁺	2.4
HCO ₃ ⁻	2.0
SiO ₃ ²⁻	0.2

Table 2-4. Experimental set-up and BET surface areas for the rock material.

Sample	Rock material (g)	BET (m ² /g)	SGW (mL)	m ² /mL SGW
HV R _d	18.19	0.2159	60.00	0.06550
HV isotherm	1.365	0.2159	4.500	0.06550
M R _d	20.00	0.1964	60.00	0.06550
M isotherm	1.500	0.1964	4.500	0.06550

SrCl_2 was added to the SGW to obtain solutions with the following Sr concentrations: 10^{-5} mol L⁻¹ for the determination of the distribution coefficients (presented in Section 3.6.1), and 10^{-2} , 10^{-3} , 10^{-4} , 10^{-5} , 10^{-6} mol L⁻¹ for the isotherm determinations (presented in Section 3.6.2). Strontium from the slow leaching (dissolution) of the mineral samples affected the analysis, and attempts were made to correct for this effect by measuring blank samples, described in the next section. After the addition of strontium, the pH of the distribution coefficient solutions was adjusted by addition of suprapure HCl or NaOH to 8.2 to reflect natural pH-conditions, while for the sorption isotherm solutions the pH was adjusted to approximately 6 in order to avoid removal of Sr from the solution through formation of SrCO_3 , which precipitates between pH 6.1 and 8 for the different Sr concentrations used.

To describe the uptake of cations the distribution ratio, R_d , is commonly defined as the ratio between the amount of cations sorbed either per weight or surface area of the solid (q) and the remaining cations in the aqueous phase (C). When the sorption system reaches an equilibrium state the distribution ratio becomes the equilibrium distribution coefficient, K_d . Because the samples were weighted so as to acquire the same surface area rather than comparing the same mass, the adsorption density, q , is defined as the amount of cations sorbed per unit surface area of solid:

$$R_d = q/C = (V/SA) \cdot (C_0 - C_t)/C_t$$

where V = volume of solution (cm³); SA = surface area of solid phase (m²); C_0 = initial [Sr²⁺]; C_t = [Sr²⁺] at time t . This equation was used for the adsorption and desorption experiments described below. The precision of the calculated distribution coefficients, based on the precision in the analyses of the aqueous solutions, was ± 50 cm³/m².

2.7.1 Adsorption

All samples were prepared in duplicate sets. Blank samples were prepared both in Sr-free SGW to monitor Sr in the aqueous phase due to leaching from the rock material and without rock in Sr-containing SGW to see if any Sr adsorbed to the container walls.

To even out concentration gradients (homogenise) all samples were placed on a shaking table after addition of the solutions. The samples were mixed continuously the first 2 hours and thereafter for 1 min every hour during the first 24 hours followed by 1 min every 2 hours for the remaining 34 days of the experiment. 500 µL sub-samples for the distribution coefficient samples were taken and diluted 10 times to a total volume of 5 mL approximately at 1, 3.5, 5.5, 7.5, 25, 73.5, 169, 336.5, 504, 672 and 840 hours after the initial addition of the Sr-containing SGW and acidified with concentrated HNO₃ (1%volume). Samples from the isotherm solutions were only taken once; after 35 days.

2.7.2 Desorption

The Sr-containing SGW was removed after 35 days and all samples were washed in MilliQ water to remove non-sorbed strontium. Sr-free SGW was then added to the samples to initiate the desorption phase. Because strontium has been found to sorb mainly through ion exchange processes (Park and Hahn 1999) a sequential chemical extraction was applied on the distribution coefficient samples during the desorption using first SGW for 21 days (eight samplings), then 0,5 M CaCl₂ (one sampling) and finally 0,5 M KCl (one sampling) for 1 week each. The isotherm solutions were kept in SGW and sampled once; after 35 days.

Measurements of blank samples (described in the previous section) were used to correct the measured concentrations.

2.7.3 pH and chemical analysis

pH was measured at each sampling event with a pH-meter. All aqueous samples were analysed at Stockholm University for Sr, Al, Fe and Mg (not presented due to experimental problems) with an ICP-OES (Varian Vista) using external calibration curves.

3 Results and discussion

3.1 Composition and rock classification

The drill core samples crushed with the two different methods were first thought to differ in chemical and mineral composition due to their visual appearance. However, the results from the investigation combining mineral determination using point counting on thin sections (Figure 3-1) and analyses of chemical composition performed at ALS Scandinavia AB in Luleå (Figure 3-3) showed only small differences between the samples.

3.1.1 Mineral composition

Point counting of the two thin sections prepared from the drill core samples demonstrates four major minerals – plagioclase ($\text{NaAlSi}_3\text{O}_8 - \text{CaAl}_2\text{Si}_2\text{O}_8$), quartz (SiO_2), K-feldspar (KAlSi_3O_8) and biotite ($\text{K}(\text{Mg}, \text{Fe})_3(\text{AlSi}_3\text{O}_{10})(\text{F}, \text{OH})_2$) – composing 93.0 and 94.5 vol.% of the HV and M samples respectively, see Figure 3-1 and Table A1-12 in Appendix A1.2. The total amount of feldspars is quite similar for the two drill core samples with 66.8 vol.% for HV and 64.2 vol.% for M. The distribution between plagioclase and alkali feldspars on the other hand differs. K-feldspar is more common in the HV sample compared to M while plagioclase shows the opposite behaviour. Furthermore, the M sample contains more quartz and the HV sample more biotite even if the difference for the latter is small (<2%).

3.1.2 Rock classification

The results from the point counting were used to classify the rock according to the IUGS (International Union of Geological Sciences) classification. There are different diagrams for classification based on the texture of the rock and because all grains in the rock were visible without the aid of a microscope the texture is said to be phaneritic (coarse grained) leading to the use of the diagram (Figure 3-2).

As can be seen in Figure 3-2, the rock from both depths, 38 m (HV) and 40 m (M), would be classified as quartz monzodiorite even if the latter is somewhat of a borderline case.

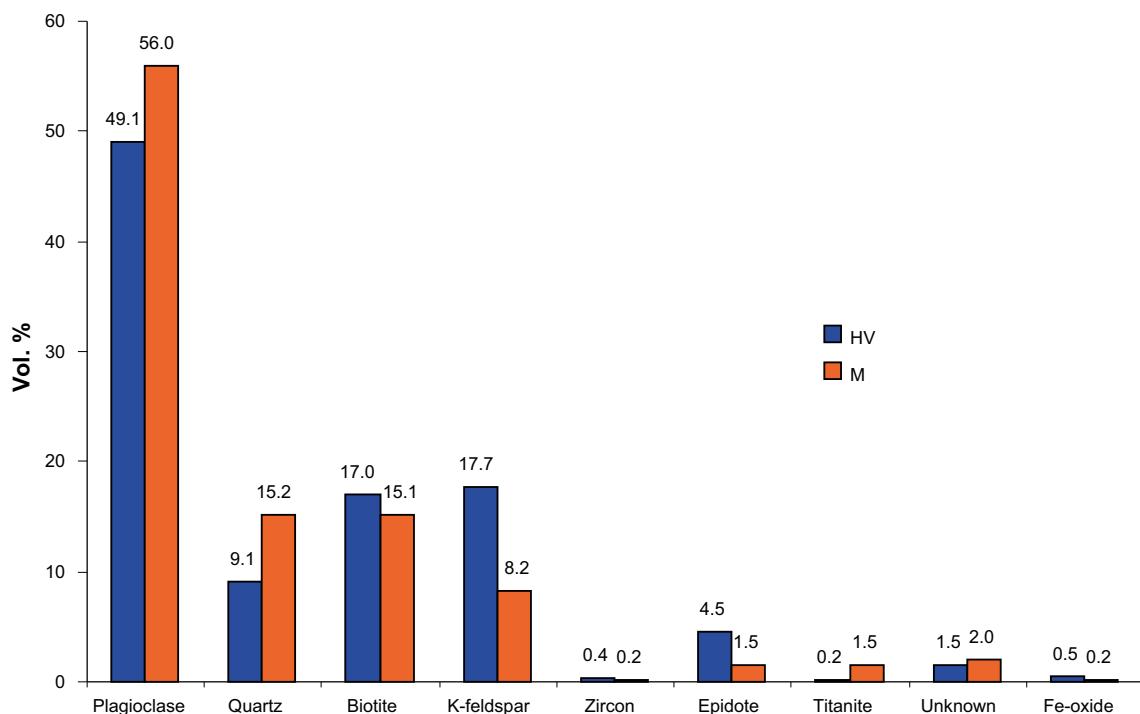

Figure 3-1. The mineral composition of the two drill core samples determined by point counting from thin sections.

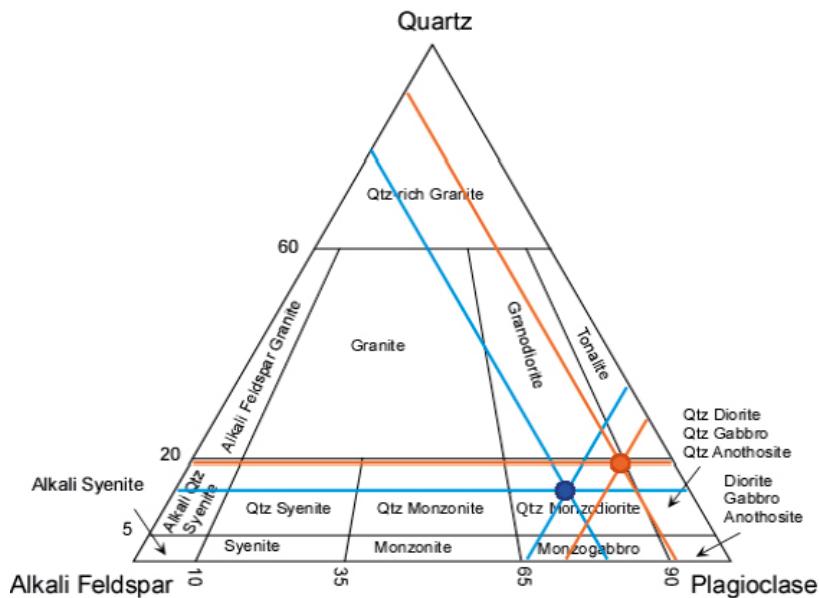

Figure 3-2. IUGS classification of the rock samples. Blue = HV, orange = M.

3.1.3 Chemical composition

Iron and magnesium

The chemical analysis for the unsieved whole rock samples (Figure 3-3) shows that the M sample contains more Fe and Mg than the HV sample which is indicative of larger biotite abundance. This is not detected for the 0.5–1.0 mm samples where the differences in concentrations are negligible.

Furthermore, both the HV and M 0.5–1.0 mm samples have lower Fe compared to the whole rock samples. An explanation for this could be accumulation of some mineral(s) in other size fractions. In the 0.5–1.0 mm size fraction, the selective removal of Fe-containing minerals during crushing/fragmentation is greater for the M sample (~40% decrease in Fe_2O_3) than for the HV sample (~25% decrease). Along with a decrease in Mg for the M samples, this ultimately results in total compositions for the two samples that are less than 5% different from each other (evening out of concentration differences compared to the drill core samples mentioned above). This suggests that the two crushing methods have led to different accumulation of minerals during fragmentation of the rocks.

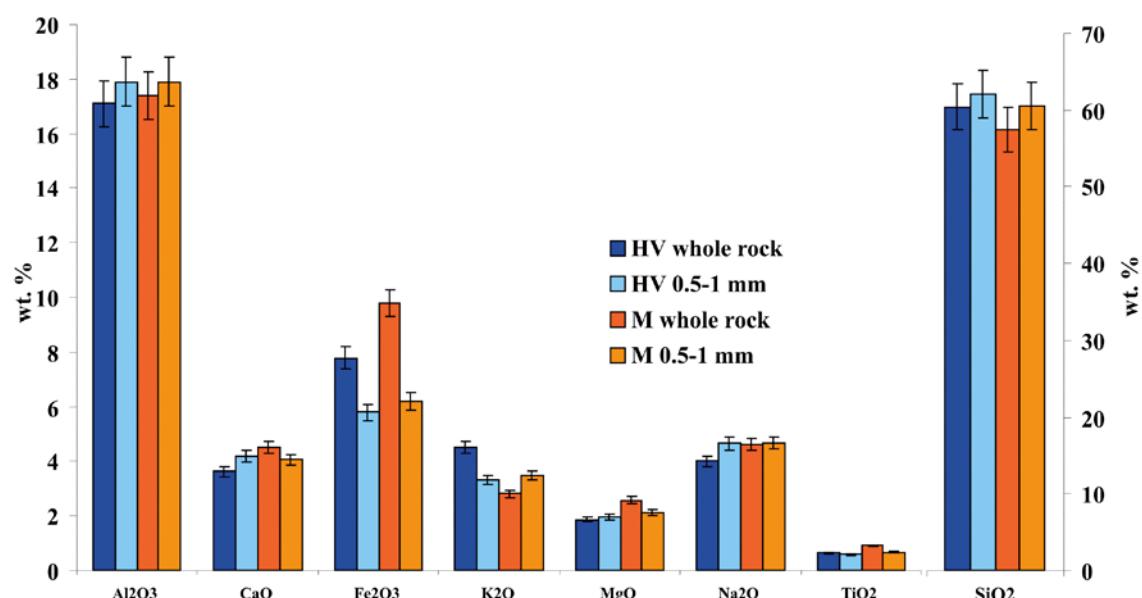

Figure 3-3. Chemical composition of the HV and M whole rock samples (crushed and unsieved drill core sample) and 0.5–1 mm size fraction samples. Error bars of ±5% are included.

However, to confirm this assumed fractionation of mineral(s) in other size fractions, all size fractions should have been investigated. Furthermore, it is noticeable that the HV material has no difference in Mg between the whole rock and 0.5–1.0 mm size fraction samples which would be hard to explain if the decrease in Fe was solely attributable to a decrease in the amount of biotite (which probably accumulates in the finer fractions) as this mineral is easily fragmented and contains both Fe and Mg. The lower Fe content of the crushed samples could therefore in addition be due to a fractionation of epidote and/or titanite, which contain Fe but negligible Mg, and are relatively resistant (less affected by crushing), leading to accumulation in the coarser fractions. The decrease in Fe could be an effect of a lesser amount of Fe-oxide in the crushed sample but since its occurrence in the whole rock is low (≤ 0.5 vol%) this is not very likely.

Potassium, sodium and calcium

For the unsieved whole rock drill core samples, potassium is more abundant in the HV sample (Figure 3-3) which could be due to a larger K-feldspar occurrence in the HV than the M drill core (see Figure 3-1). However, K also occurs in biotite and therefore it is difficult to draw any further conclusions. Potassium increases in the M 0.5–1 mm size fraction and decreases for the HV sample compared to the whole rock drill core sample. This could be an effect of selective accumulation of biotite and/or K-feldspar in different size fractions.

For the unsieved whole rock drill core samples both Ca and Na concentrations are greater in the M sample (Figure 3-3) indicating that M contains more plagioclase. Both elements have increased in the HV 0.5–1.0 mm size fraction which implies accumulation of plagioclase in this fraction while Na in the M sample are practically the same for the whole rock drill core sample and the crushed sample and the concentration of Ca somewhat lower in the 0.5–1 mm fraction.

3.1.4 Conclusions and suggested improvements

The chemical analysis of the unsieved whole rock drill core and the 0.5–1 mm fraction samples and the mineral identification through point counting from the drill core thin sections has led to somewhat different results as can be seen in the summarizing Table 3-1 and Table 3-2. This is an indication of either unrepresentative samples, unreliable methods or both. As mentioned in Chapter 1, the samples are small and the rock type heterogeneous, coarse-grained and porphyritic, which evidently have had effect on the different chemical and mineralogical composition of the samples used for the two methods.

It is possible that crushing the rock has led to the accumulation of some minerals in different size fractions, see Table 3-2, as Fe and Mg have decreased in the 0.5–1.0 mm M sample compared to the whole rock samples whereas Ca and Na have increased in the crushed fraction for the HV sample. For the M material this suggests an accumulation of biotite in either larger or smaller size fractions (most likely smaller due to the brittleness of the mineral), although biotite alone cannot explain the preferential loss of Fe over Mg. Plagioclase may have accumulated in the 0.5–1.0 mm fraction for HV. Without further analyses of additional size fractions it is hard to establish any correlations between particle size and mineral occurrence. However, both crushing methods may have led to the accumulation of different minerals, but in different manners, which indicate that both methods are incapable of producing samples that are representative for the bedrock regarding the chemical composition.

For more reliable results several thin sections should have been prepared and several size fractions as well as larger samples used for chemical analysis to reduce the risk of unrepresentative samples.

Table 3-1. Largest occurrence of different minerals in the drill core thin sections analysed for chemical composition as indicated by the sample name.

	K-feldspar	Plagioclase	Biotite
Chemical analysis	(HV)	M	M
Point counting	HV	M	HV

Table 3-2. Differences in mineral occurrence in the 0.5–1 mm size fraction compared to the drill core samples as interpreted from the chemical composition analyses.

	K-feldspar	Plagioclase	Biotite
M	Small increase	No difference/small decrease	Decrease
HV	Small decrease	Increase	Contradictive results

3.2 N₂ adsorption isotherm and pore size distribution

3.2.1 Classification of adsorption isotherms

The N₂ adsorption isotherms are very similar for the HV and M samples for all size fractions, see example in Figure 3-5, and all isotherms in Appendix 2. They all correspond to the IUPAC (International Union of Pure and Applied Chemistry) classification type IV isotherm (Figure 3-4 left) that show a characteristic hysteresis loop which is associated with mesopores (20–500 Å). The hysteresis loop may exhibit different shapes (Figure 3-4 right) which are thought to be related to the pore structures. It is not completely straightforward to identify the type of hysteresis loop due to the lack of scale in the IUPAC figures but in this case it should be either type H3 or H4. Since H3 is a type observed for aggregates and H4 corresponds to narrow slit-like pores it is H4 that should be the most correct one for the samples in this study (Sing 1982). The desorption curve in Figure 3-5 shows lower amount adsorbed (line with crosses) than the adsorption curve in the end of the adsorption at low relative pressure. This could be due to weathering and release (desorption) of Sr already attached to the samples prior to the experiment, although in very low amounts.

3.2.2 Pore size distribution (PSD)

The pores were divided first into two groups; ca 15–800 Å and >800 Å (Figure 3-7) as reported in the DFT results. The complete PSD of pores with sizes 15–800 Å can be seen in Figure 3-9 to Figure 3-12 and will be discussed further down.

Reports from measurements of the PSD according to DFT can be found in Appendix 2.

A conceptual presentation of common porosity features is found in Figure 3-6.

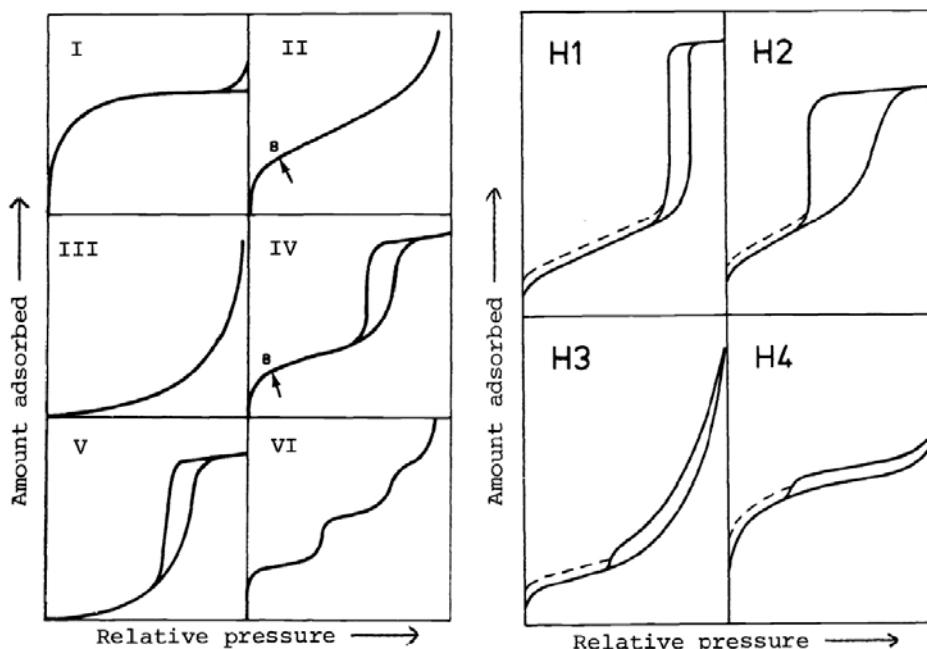

Figure 3-4. Types of physisorption isotherms (left) and of hysteresis loops (right) (from Sing 1982).

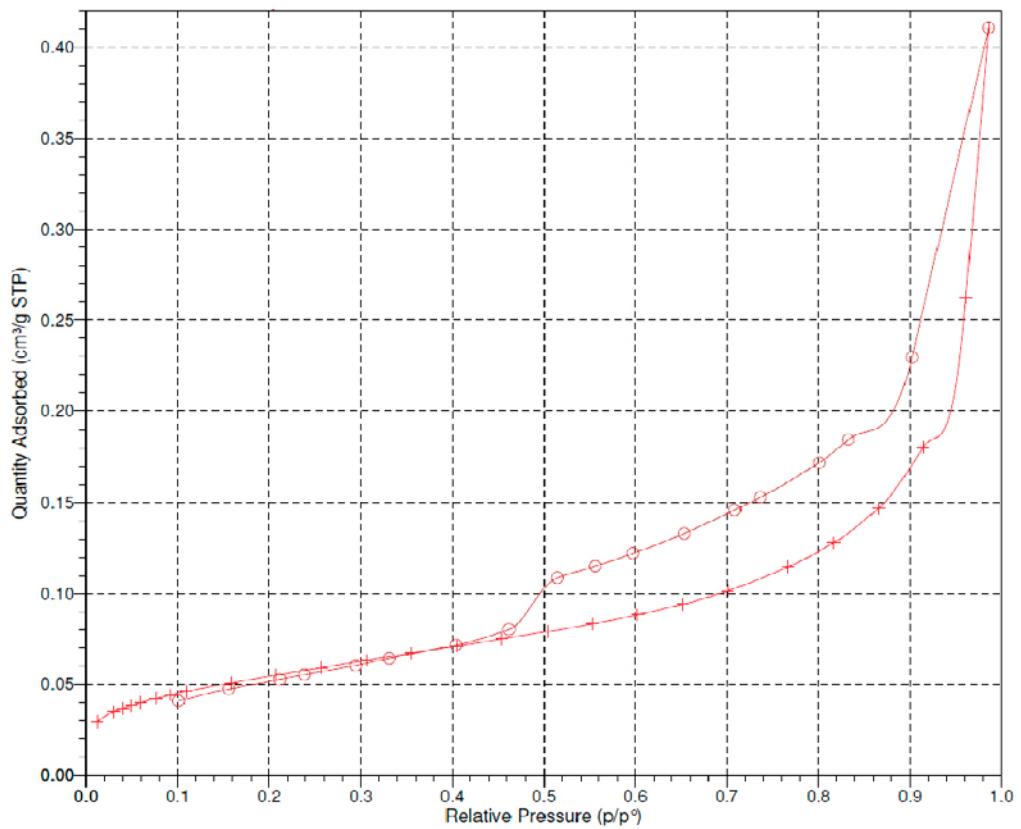

Figure 3-5. Isotherm plot for the M 0.5–1 mm sample.

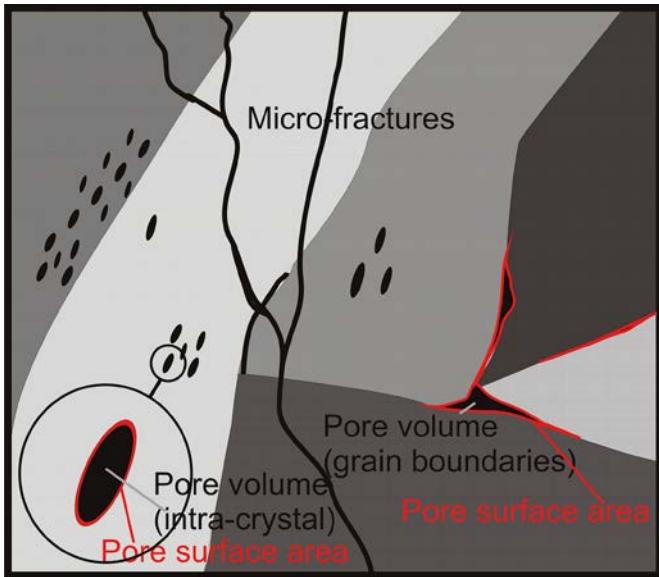

Figure 3-6. Conceptual presentation of porosity features in the rock mass: intra-crystal porosity (with close-up of pore surface area and pore volume), pore volume and pore surface area between grains and micro-fractures through different mineral crystals and along grain-boundaries. Different mineral grains are shown with different colour.

Pore sizes 15–800 Å and >800 Å

For the M sample the surface area for pores with sizes 15–800 Å decreases somewhat with increased particle size over the three smallest size fractions, see Figure 3-7. The 2.0–3.0 mm fraction, on the other hand, opposes this trend. The surface area for pores >800 Å also generally decreases with size from the smallest to the largest fraction for the M sample and what is striking is that these pores are almost non-existing in the 2.0–3.0 mm size fraction. Looking at the percentage distribution between pores of these two size groups (Figure 3-8) one can see that it is very similar for the three smallest fractions with ca 12–14% for pores with sizes 15–800 Å and ca 76–78% for pores exceeding 800 Å. Due to the very small amount of pores >800 Å for the 2–3 mm the smaller pores represent approximately 97% of the total amount.

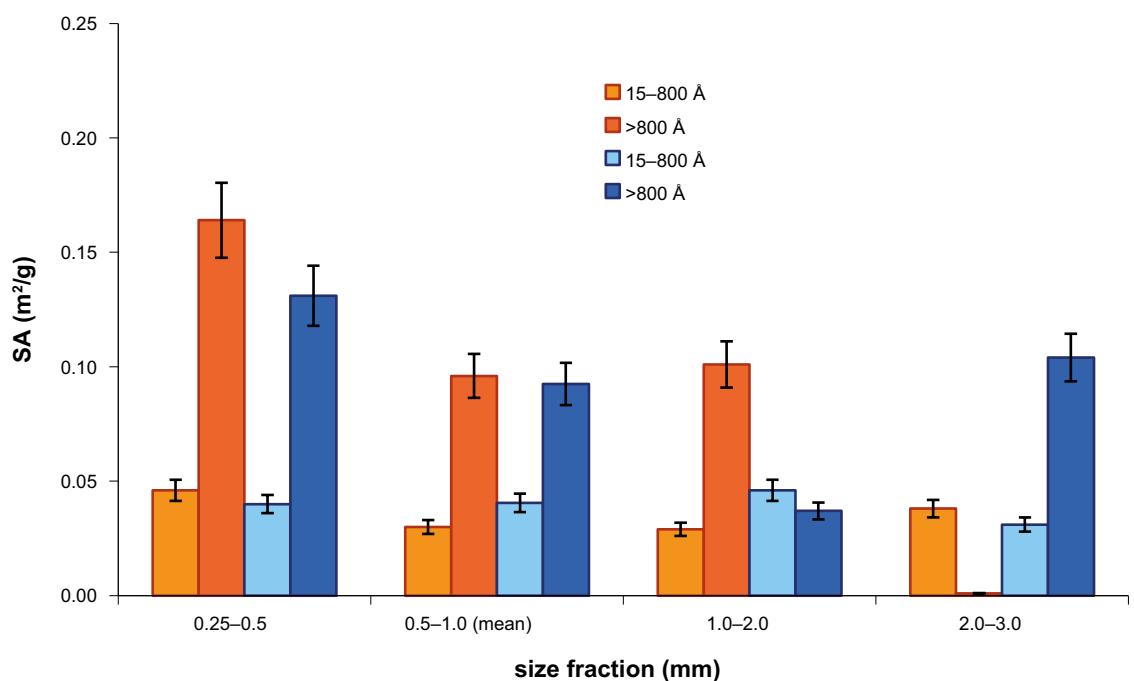

Figure 3-7. PSD for sizes >800 Å and 15–800 Å. Blue = HV, orange = M. The values for the 0.5–1 mm fraction are mean values from two measurements. The actual values were $0.0405 \pm 0.0035 \text{ \AA}$ (HV) and $0.0300 \pm 0 \text{ \AA}$ (M) for pores in the range 15–800 Å and $0.0925 \pm 0.0015 \text{ \AA}$ (HV) and $0.096 \pm 0.0040 \text{ \AA}$ (M) for pores exceeding 800 Å. Error bars show $\pm 10\%$.

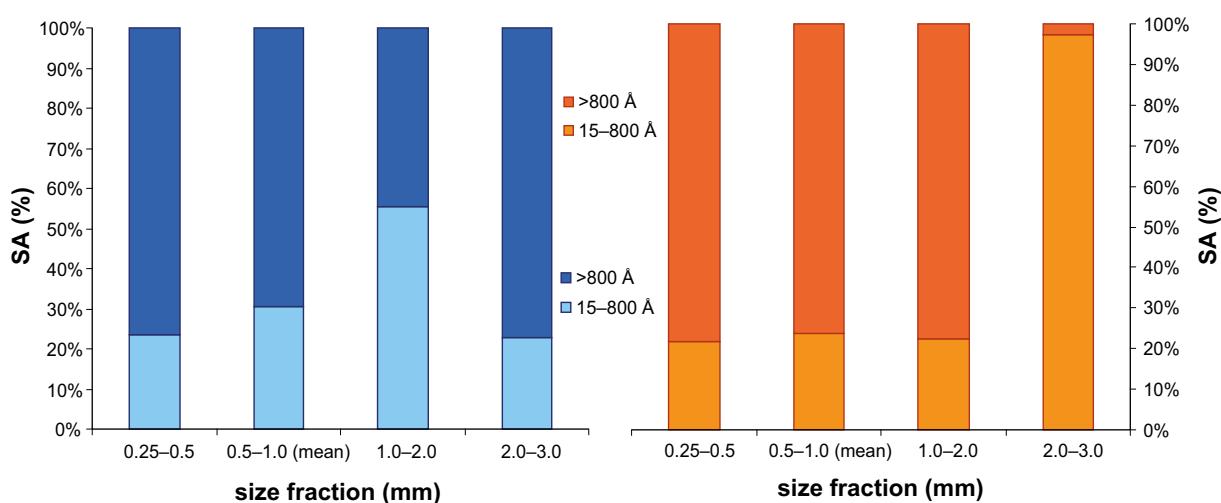

Figure 3-8. Percentage distribution of pores >800 Å and 15–800 Å. Blue = HV, orange = M.

The surface area for pores with sizes 15–800 Å is increasing with increasing grain size for the three smallest fractions of HV samples (opposite behaviour compared to the M samples). On the other hand, the pores exceeding 800 Å for the same fractions decrease, see Figure 3-7, leading to an increased percentage of pores between 15 and 800 Å for HV (Figure 3-8) (although the variability change is generally within 10%). The 2.0–3.0 mm fraction is deviating from this trend since the values of surface area for pore sizes 15–800 Å decrease while the value for pores exceeding 800 Å increases compared to the 1.0–2.0 mm size fraction.

Both HV and M samples show trends of decreasing amount of total pores with increased particle size with the exception of the HV 2.0–3.0 mm sample that has an amount about equal to the HV 0.5–1 mm fraction.

PSD of pore sizes 15–800 Å

Regarding the pores between 15 and 800 Å, the distribution can be seen in Figure 3-9 to Figure 3-12 below. All samples have a significant amount of mesopores (20–500 Å) which is consistent with the IUPAC type IV isotherm discussed in Section 3.2.1.

Pores with sizes 15–20 and 20–40 Å show no consistent difference between the HV and M samples (Figure 3-9 to Figure 3-12), showing distribution of pore surface area over different pore width. The duplicate measurements indicate largest pore size variations in these areas and up to ca 90 Å (Figure 3-10). It is possible that the washing of the samples prior to analysis was not sufficient enough to remove all dust particles leading to these variations. However, for pores with the sizes 90–800 Å the surface area is largest for the HV sample in all cases, see Figure 3-13 (although the difference in the smallest and largest fractions are within the 10% uncertainty of the method), and similarly in the 230–800 Å size span. Furthermore, both the HV and M 0.25–0.50 mm samples show a positive deviation from the other grain sizes in the 230–800 Å size span (Figure 3-13, Figure 3-14, and Figure 3-15), although the M sample is within the 10% uncertainty of values from other grain sizes. The values are 0.020 (HV) and 0.018 (M) m²/g for the 0.25–0.50 mm fraction compared to 0.017 m²/g and 0.013 m²/g for all the larger fractions of the HV and M samples respectively. No other significant differences could be established between the two crushing methods from the pore size distribution and quantity of pores.

3.2.3 Conclusions

- Both M and HV samples show trends for the three smallest size fractions regarding the pore width groups 15–800 Å and >800 Å. For the HV samples the total surface area of pores >800 Å decreases with increased particle size while the surface area for smaller pores (15–800 Å) increases slightly (note that increase is smaller than method error). The M samples generally show a decrease in both 15–800 Å and <800 Å pores from the 0.25–0.50 Å to the two larger fractions leading to a very similar percentage distribution (Figure 3-8). The 2.0–3.0 mm fraction deviates for both HV and M samples, perhaps due to dominance of resistant K-feldspar phenocrysts. Since the surface area for both pore width groups differ for both samples between the grain sizes alteration and/or selectivity is likely to have occurred during both crushing procedures.
- None of the crushing methods have created grains that show similar pore size distributions over the entire spectra of grain sizes (Figure 3-14 and Figure 3-15). This indicates that both crushing methods have led to alteration of the rock.
- The samples crushed with high voltage have more pores compared to the M samples from 90 to 800 Å for all grain sizes, see Figure 3-13. This could indicate that the high voltage crushing is less capable of producing unaltered samples than mechanical crushing but could also be an effect of different starting conditions.
- The fact that the 0.25–0.50 mm size fraction has the largest surface area for the pore width range 230–800 Å might be an indication that pores in this range are formed during continued treatment with both methods. Since the other grain size fractions are more similar to each other in this region it is possible that this effect only occurs after a certain amount of treatment and that the larger grains are unaffected.

Suggestion for further studies: Preferably, further N₂ adsorption measurements would be performed on intact bedrock to compare with the results for the crushed samples to make sure that the observed differences in not an effect of different starting conditions. Larger pores will be discussed further in Section 3.3 (visual investigation with SEM) where comparisons with the drill cores are also made.

3.3 Studies of fracturing and alteration using a Scanning Electron Microscope (SEM)

3.3.1 Intact drill core samples

The presence of pores varied to some extent for the two drill core samples; from rather low occurrence (Figure 3-16), to more affected grains (Figure 3-17). Overall there were more grains with a larger occurrence of pores and cracks in the M than the HV drill core samples. The interpretation of larger number of pores in the M sample is however slightly uncertain as this thin section is less evenly polished than the HV sample.

Two types of grain boundaries could be found in both drill core samples. Type I where the minerals were closely attached without any fracturing between them, see Figure 3-17. Type II where fractures occur between the minerals, see Figure 3-18.

3.3.2 M sample, 2.0–3.0 mm fraction

In this sample it is easy to find quartz and feldspar grains with a relatively small amount of visible pores (Figure 3-19). It is possible that these grains have been more resistant to the mechanical crushing and therefore are more common in the largest fraction (than in smaller fractions described below). The low amount of pores may, at least partially, explain the low value for surface area of pores exceeding 800 Å for this fraction (Figure 3-7) since the width of these pores are in the approximate range of 0.1–2 µm, see Figure 3-19.

For some of the mineral grains with low pore occurrence there was no difference between the fracture surface and the inner area of the grain (Figure 3-20, left) but for most of them the grain boundary had been altered through an increase in cracks with lengths in the range of several µm (Figure 3-20, right). Mechanical crushing may lead to localized strain bands with an adjacent zone of micro-cracks and that fractures form when enough micro-cracks connect (André 2009). This could lead to the formation of grains with disturbed grain boundaries with both fractures and micro-cracks.

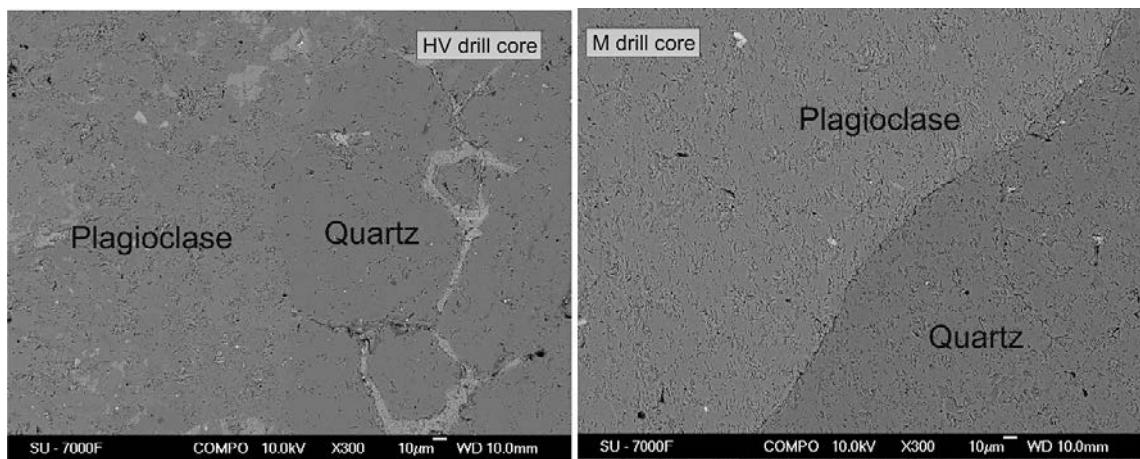

Figure 3-17. HV on the left and M on the right. Examples of quartz (right side on both pictures) and plagioclase grains (left side on both pictures) with a relatively large amount of cracks/pores. Relatively poor polishing on the right thin section. Grain boundary is of Type I.

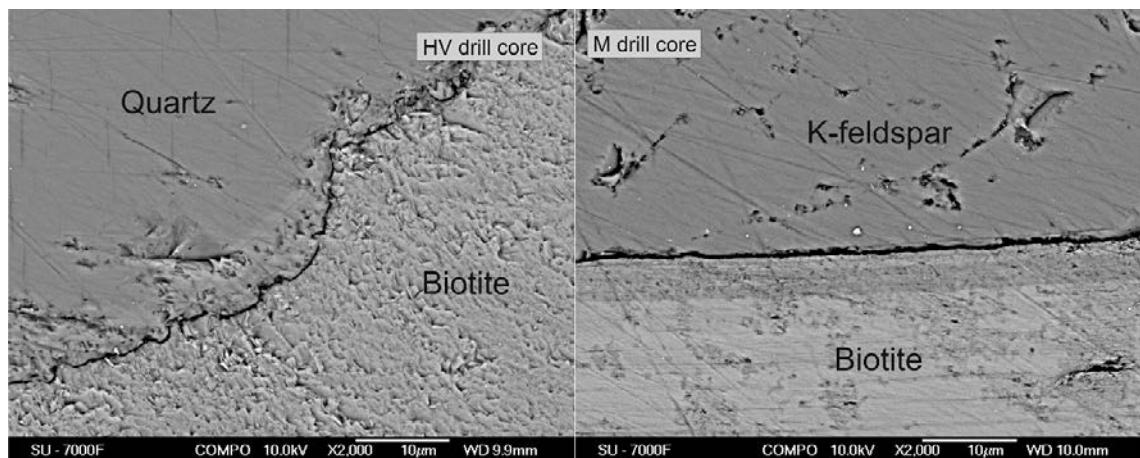

Figure 3-18. Type II, fractured grain boundaries.

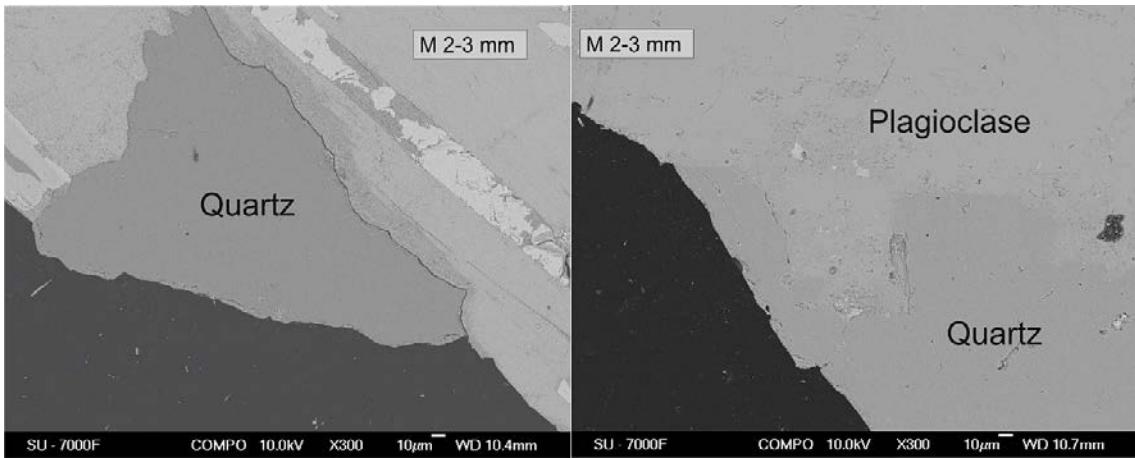

Figure 3-19. Examples of grains with low amount of pores. Dark coloured area is epoxy.

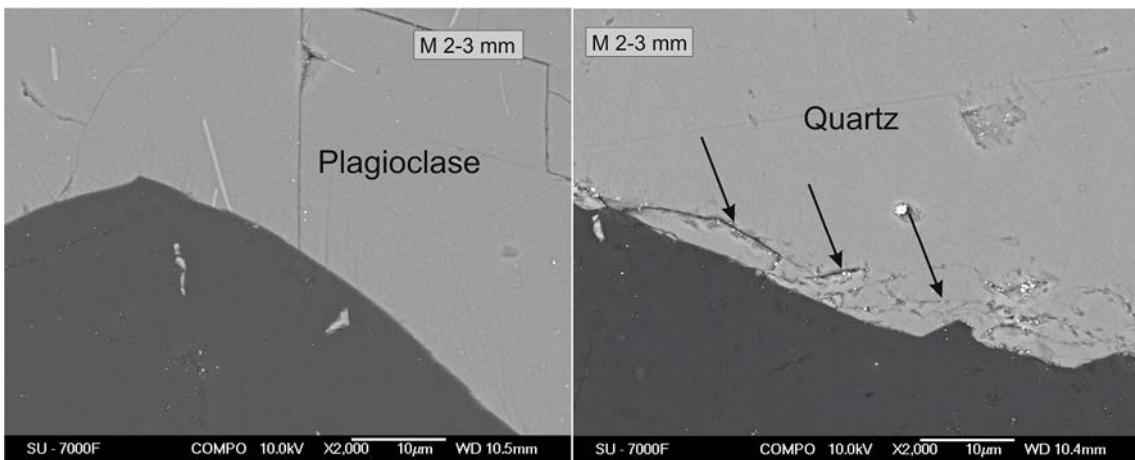

Figure 3-20. Unaltered plagioclase grain boundary on the left, affected quartz on the right.

Grains with a larger pore occurrence for quartz and feldspars were also found (Figure 3-21) even if the smoother ones dominated. The disturbed zone at the grain boundary was found on most grains examined.

Many biotite grains were markedly affected and sheets tended to separate close to the grain boundary (Figure 3-22). Less affected biotite grains were also found (Figure 3-23) even if they were not as common. Noticeable is also that the biotite grains, in similarity with feldspars and quartz, had a low pore occurrence and that the grain interiors tended to be relatively smooth.

Larger cracks, ranging from about ten up to several hundred μm were also found (Figure 3-24). These were most frequent relatively close to the grain boundaries and within grains rather than between grains. Some larger cracks were however located between mineral grains (Figure 3-25, left and Figure 3-19, left) but examples of cracks going straight through a mineral were also found (Figure 3-25, right).

Fractures in biotite grains did not only occur between sheets where the binding energy is low but also perpendicular to the cleavage plane (Figure 3-24).

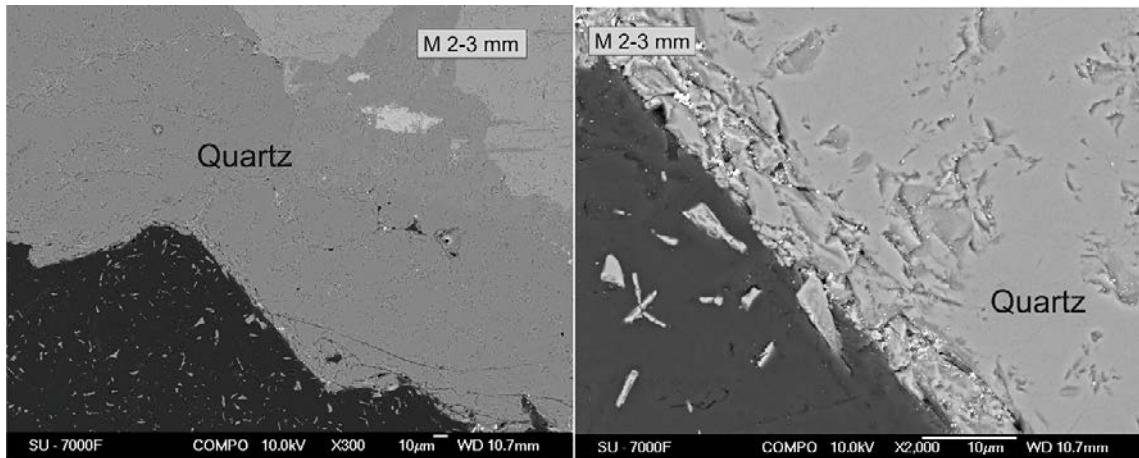

Figure 3-21. An example of quartz with larger pore occurrence. The increased amount of cracks at the grain boundary can be spotted on the right. The porous occurrence of the left quartz grain to the right is probably partially due to poor polishing at this specific area of the thin section.

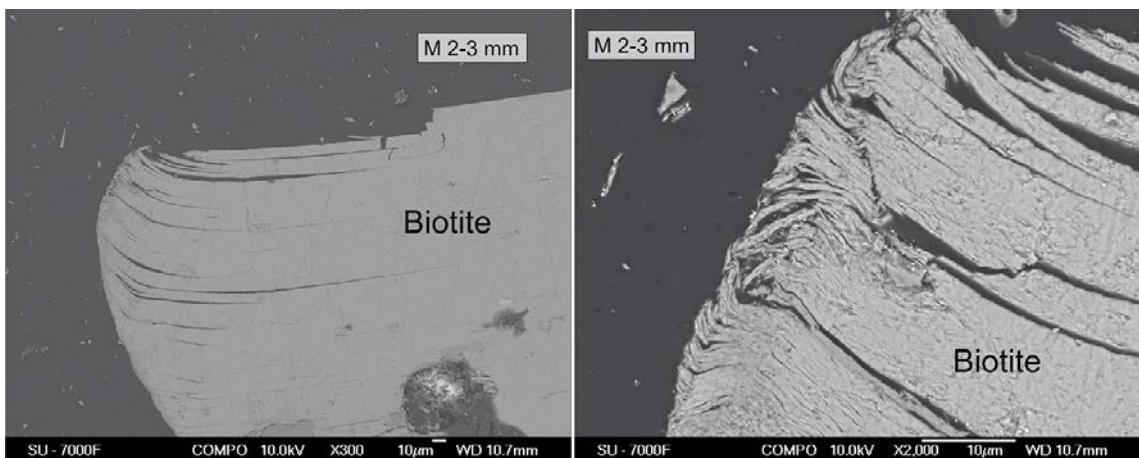

Figure 3-22. Biotite grain boundaries. Notice how the sheets separate close to the grain boundary.

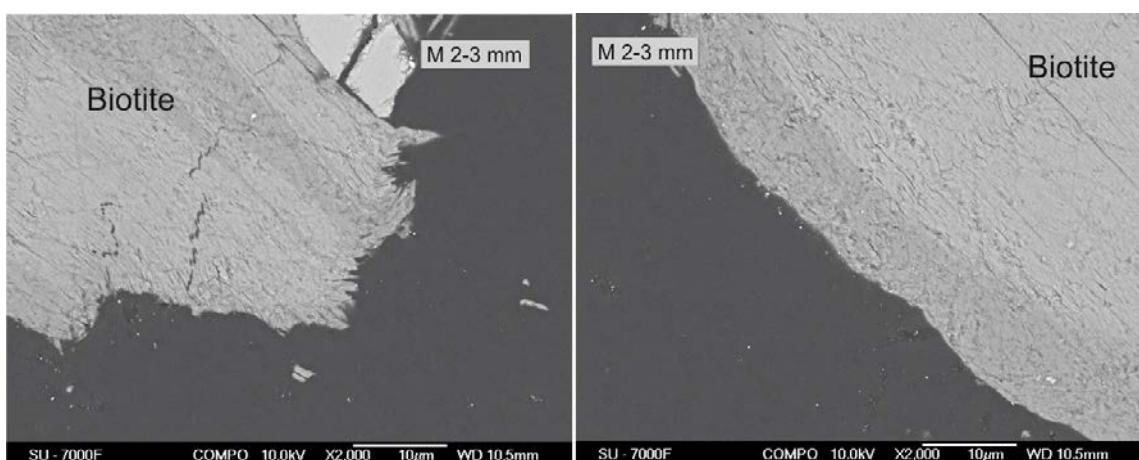

Figure 3-23. Examples of biotite that is practically unaffected at the grain boundary.

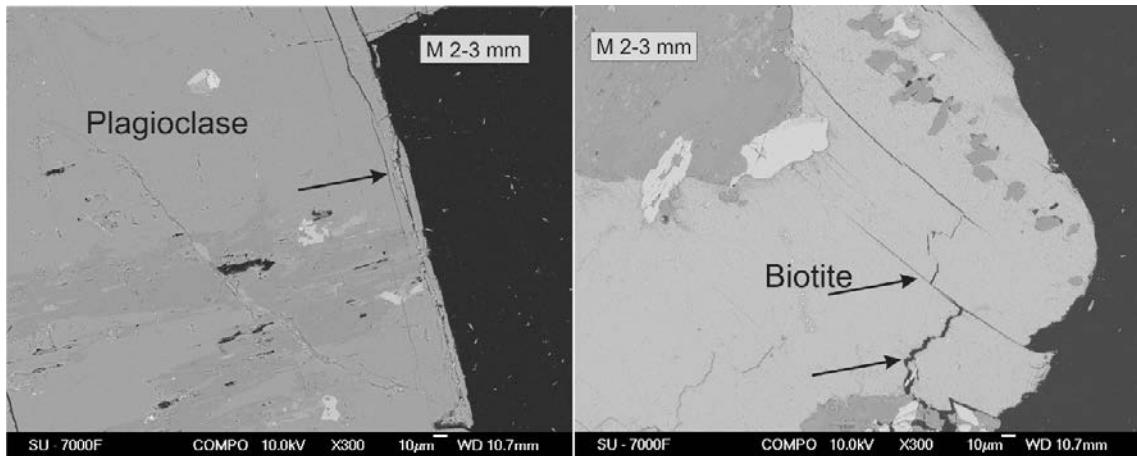

Figure 3-24. Left: plagioclase with cracks parallel to grain boundary. Right: biotite with do not only occurring between the sheets but also perpendicular to them, see also Figure 3-23, left.

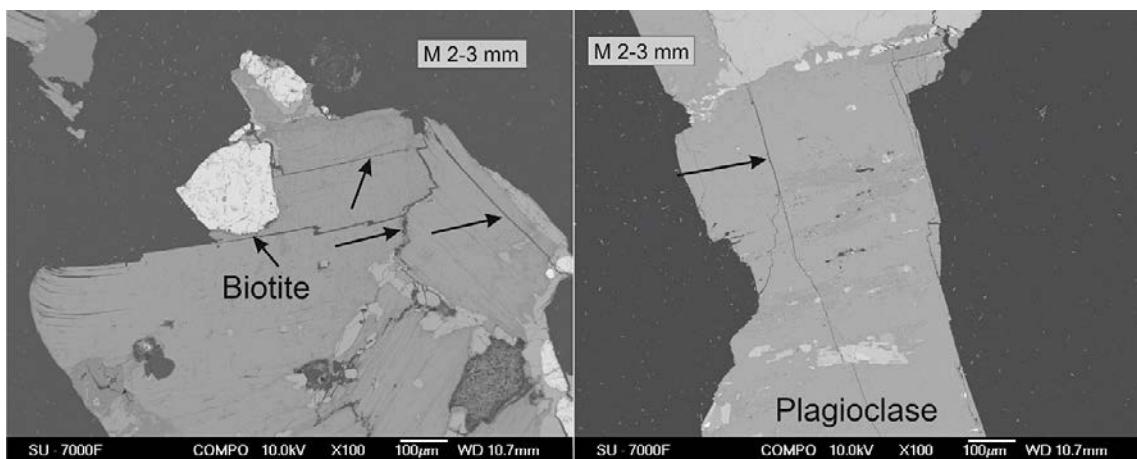

Figure 3-25. Larger cracks between biotite grains on the left and within a plagioclase grain on the right.

Summary and conclusions for M 2.0–3.0 mm

- The M 2.0–3.0 mm sample generally contains quartz and feldspar grains with a relatively small presence of pores within the grains compared to both the M drill core sample and the smaller fraction (see Sections 3.3.1 and 3.3.4). This could be an effect of these grains being more resistant to the mechanical crushing and therefore overrepresented in the larger grain fraction.
- Most grain boundaries have an increased amount of cracks compared to the interior of the grains. Since these cracks have not been spotted in the drill core sample it is possible that their appearance is an effect of the mechanical crushing subjecting the material to high stress. However, one should not exclude the possibility that at least some of these cracks may have formed during the preparation of the thin section.

3.3.3 HV sample, 2.0–3.0 mm fraction

The selectivity of grains with a low pore occurrence that was found to have happened for the M 2.0–3.0 mm sample was not seen for the HV sample partially due to that the polishing of the HV sample was less satisfactory than for the M sample making a thorough comparison between these two samples of this fraction difficult. Also, in contrast to the M sample (Figure 3-20 and Figure 3-21), most grain boundaries showed no or little increase in cracks in the μm range (Figure 3-26 and Figure 3-27).

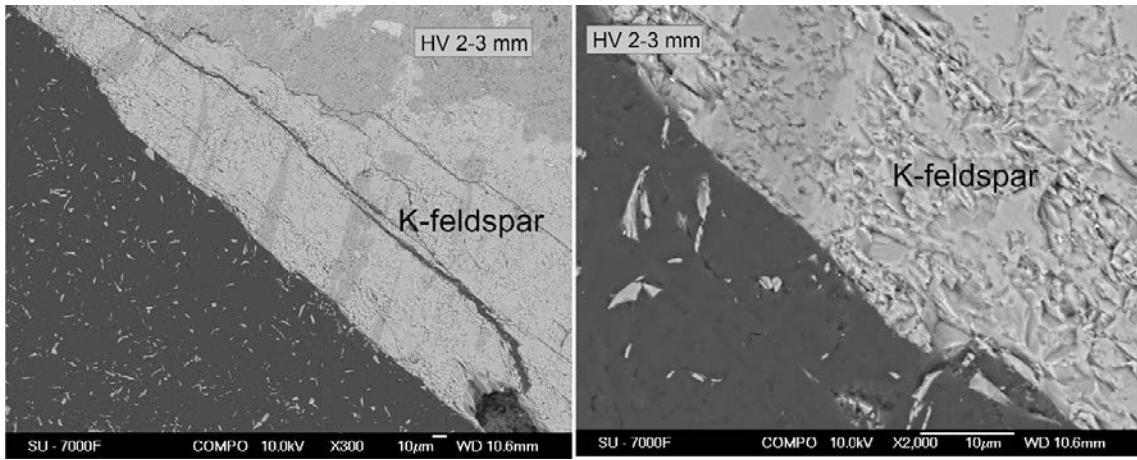

Figure 3-26. K-feldspar from the same grain boundary at different magnification. There is no sign of increased crack occurrence close to the grain boundary compared to the interior.

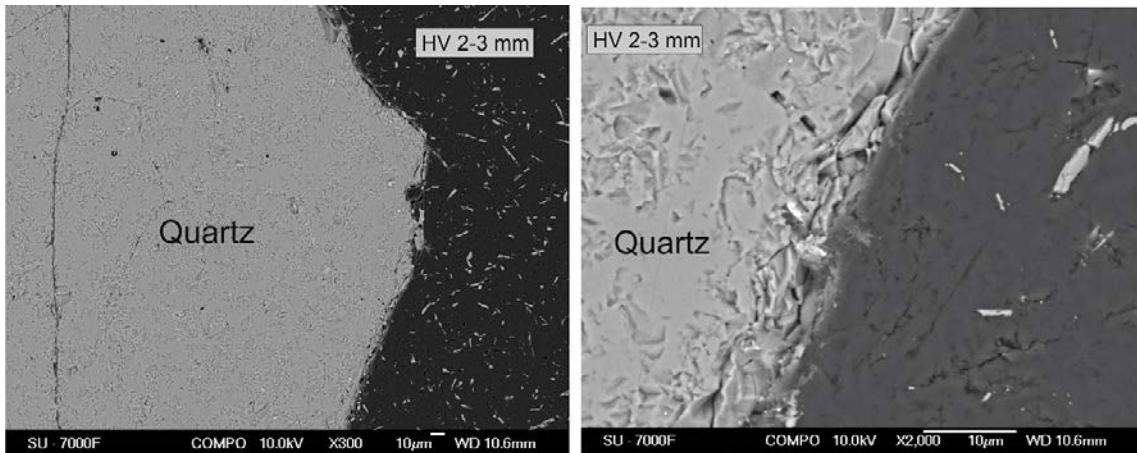

Figure 3-27. Example of quartz grain with slight increase in crack frequency close to the grain boundary. Poor polishing is observed in the highly magnified right image.

Biotite grains were less affected at grain boundaries compared to the M sample even if examples with sheet separation close to the grain boundary were found, see Figure 3-28. Regarding the grain interiors, the amount of pores was higher for the HV sample than the M sample, but due to the difference in degree of polishing between these thin sections, this observation is uncertain.

The larger fractures ranging from about ten up to several hundred µm found in the M sample were found to be even more common in the HV sample. Also, they tended to a larger extent to occur in the middle of grains (Figure 3-29) compared to the M sample. Examples where these cracks occurred more frequently close to the grain boundary were also found (Figure 3-30) even if the former were more common.

Summary and conclusions, HV 2.0–3.0 mm fraction

- For the HV sample there is no sign of selectivity of fracturing along grain boundaries of certain type of grains (as was the case for the same size fraction of the M sample, see Section 3.3.2) and no or little increase in cracks in the µm range close to the grain boundaries. Furthermore, there are fewer biotite grains with sheet separation close to the grain boundary compared to the M sample. This could indicate that the high voltage crushing is less destructive than the mechanical crushing.
- However, since the larger fractures occur to a greater extent in the HV sample it seems more likely that both crushing methods have had an altering effect on the grains even if in different manners.

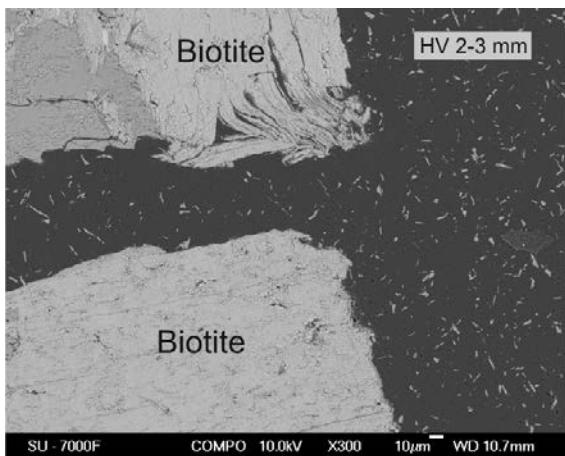

Figure 3-28. Examples of biotite grains. The lower grain shows no separation of the biotite sheets while the upper is more affected.

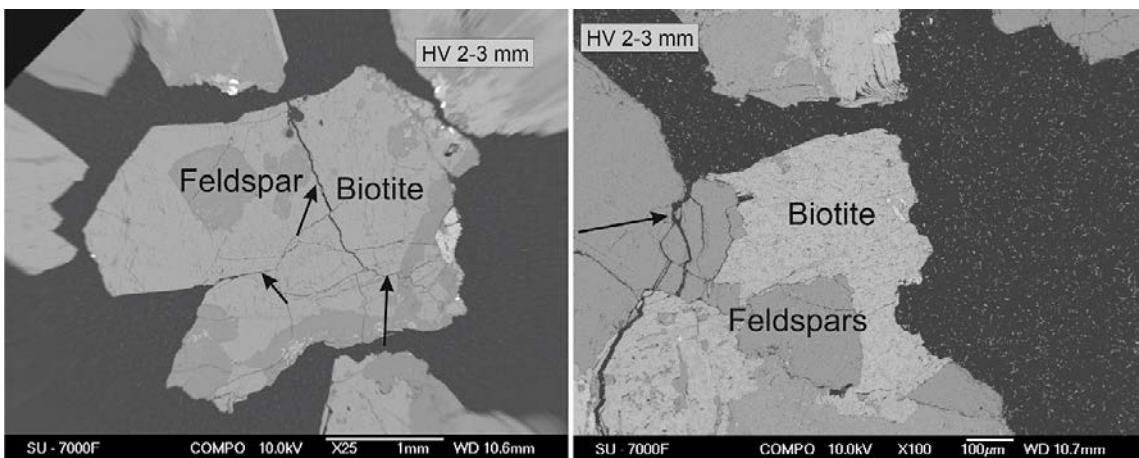

Figure 3-29. Examples of larger fractures.

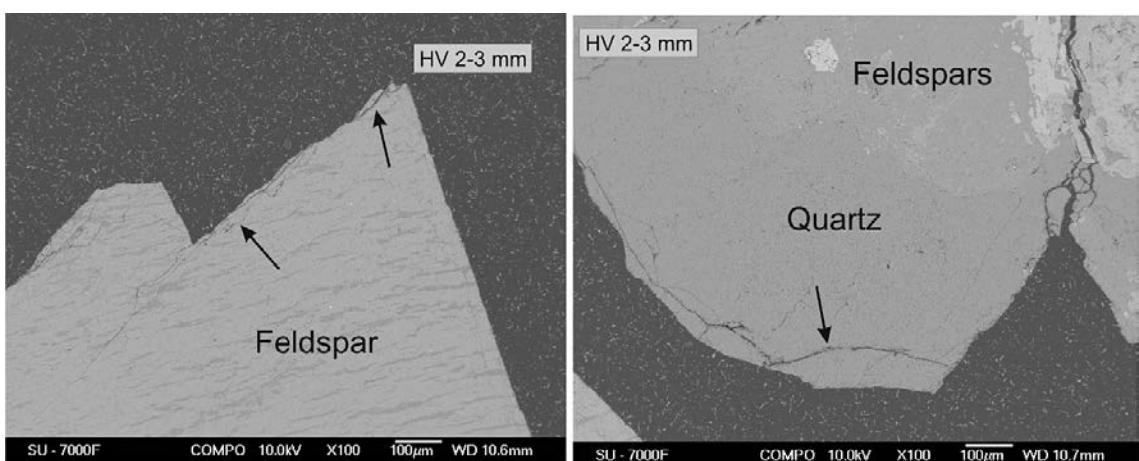

Figure 3-30. Examples of larger cracks occurring close to the grain boundary.

3.3.4 M sample, 0.5–1.0 mm fraction

The M 0.5–1.0 mm sample had a markedly different appearance compared to the larger fraction examined. Firstly, the pores in the width range of approximately 0.1–2 µm that were low in occurrence for the 2.0–3.0 mm fraction sample were found in all quartz and feldspar grains, see example in Figure 3-31. However, the polishing of this thin section is poor, and an uncertain degree of pores can be artefacts from the polishing and therefore the increase in porosity is uncertain, in contrast to micro-fracturing which is visible even if polishing is poor and which cannot be misinterpreted as artefacts from the polishing. The cracks with lengths in the µm range that were found to be present at grain boundaries in the largest fraction were not as common in the 0.5–1.0 mm fraction even if they did appear in some cases. The appearance of these cracks was also somewhat different from those in the larger fraction. The length was overall shorter and the width somewhat more narrow. Their shape together with the higher presence of pores compared to the 2.0–3.0 mm fraction made these cracks easier to spot at a higher magnification, see example in Figure 3-32 ($\times 5,000$ magnification).

Furthermore, the interior of biotite grains also appeared much richer in pores compared to the larger size fraction, see Figure 3-33, compare to Figure 3-22 and Figure 3-23, but this may to an unknown extent be due to poor polishing. There was, however, little or no tendency for the sheets to separate close to grain boundaries (Figure 3-34) compared to the 2.0–3.0 mm fraction (Figure 3-22). Larger fractures penetrating the grains were found, though exclusively between sheets (Figure 3-33 and Figure 3-34). Cracks perpendicular to sheets that were found for the larger fraction (e.g. Figure 3-23, left), were absent in the 0.5–1.0 mm fraction.

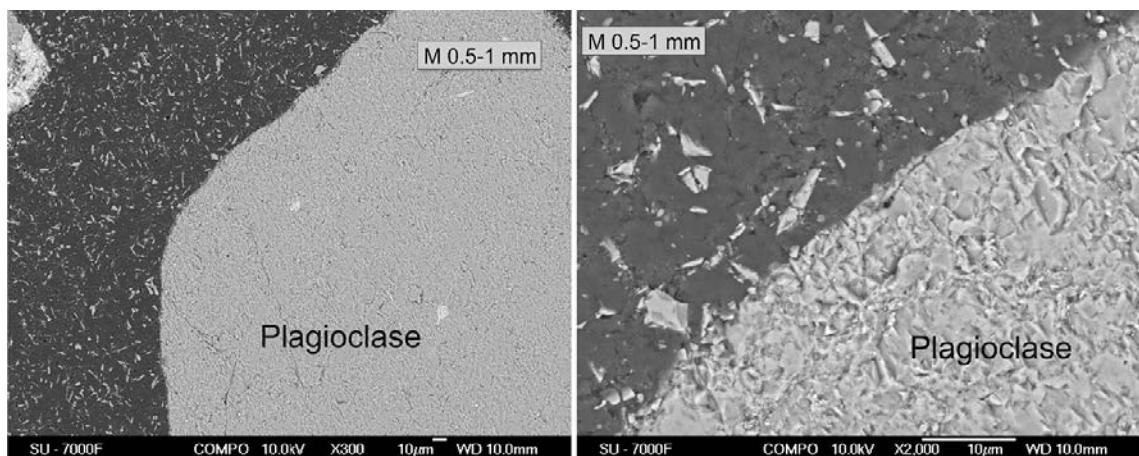

Figure 3-31. Example of a plagioclase grain. Note the large amount of pores present, although the poor polishing makes it difficult to estimate how much of this porosity that originates from poor polishing and how much that originates from the crushing.

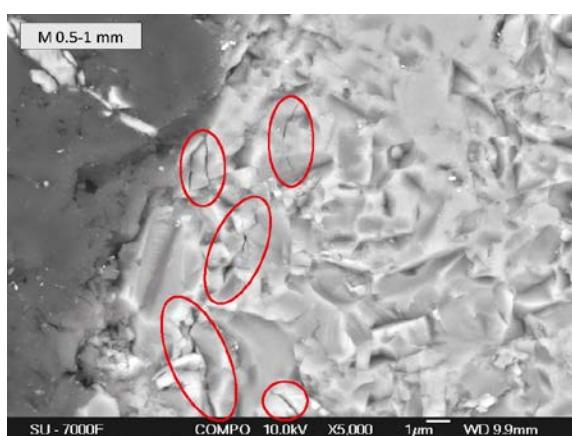

Figure 3-32. Cracks in the µm range.

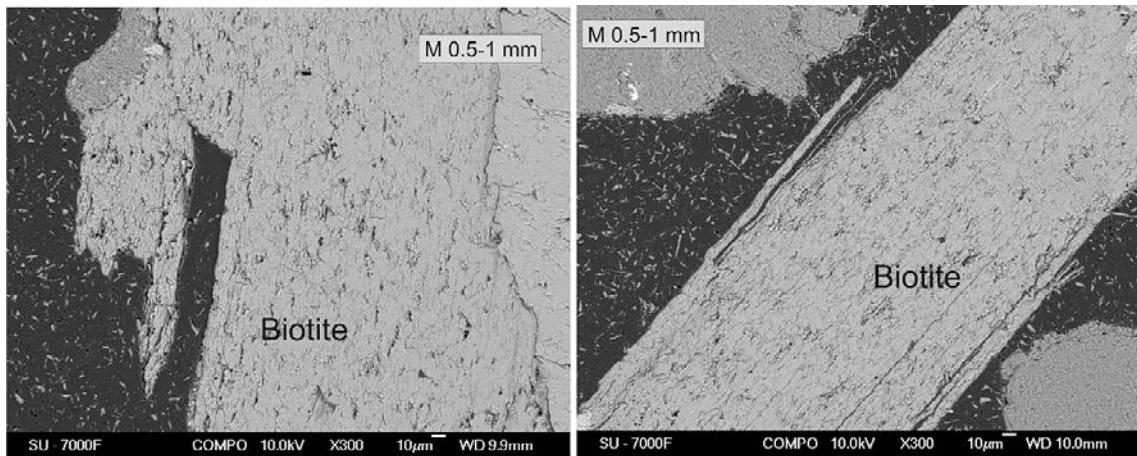

Figure 3-33. Examples of biotite grains.

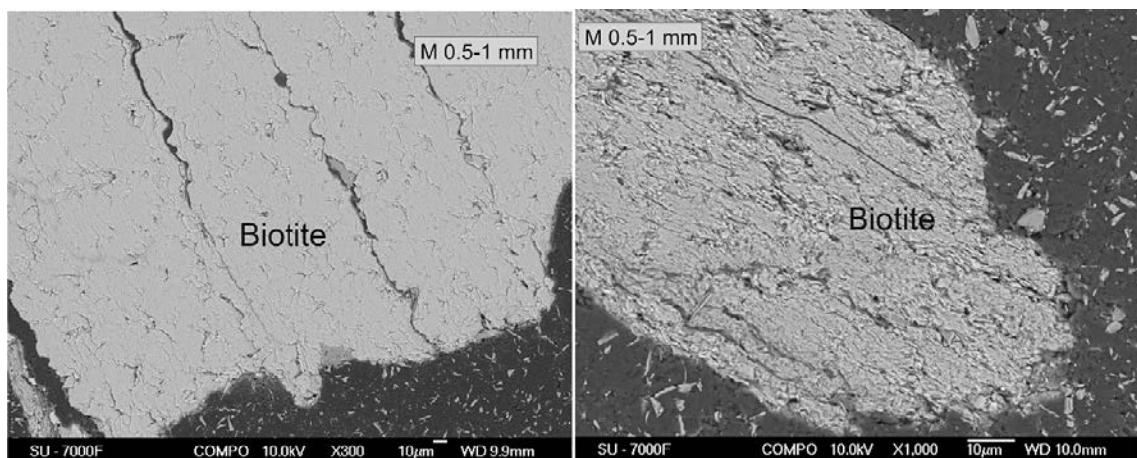

Figure 3-34. Examples of biotite grains. Note the general absence of sheet separation at grain boundaries as seen in the larger fraction.

Larger fractures were found in quartz and feldspar grains as well (Figure 3-35) though they could not be found to appear more regularly close to grain boundaries as was the case for the larger fraction. They occurred both randomly and along cleavage planes for feldspar minerals.

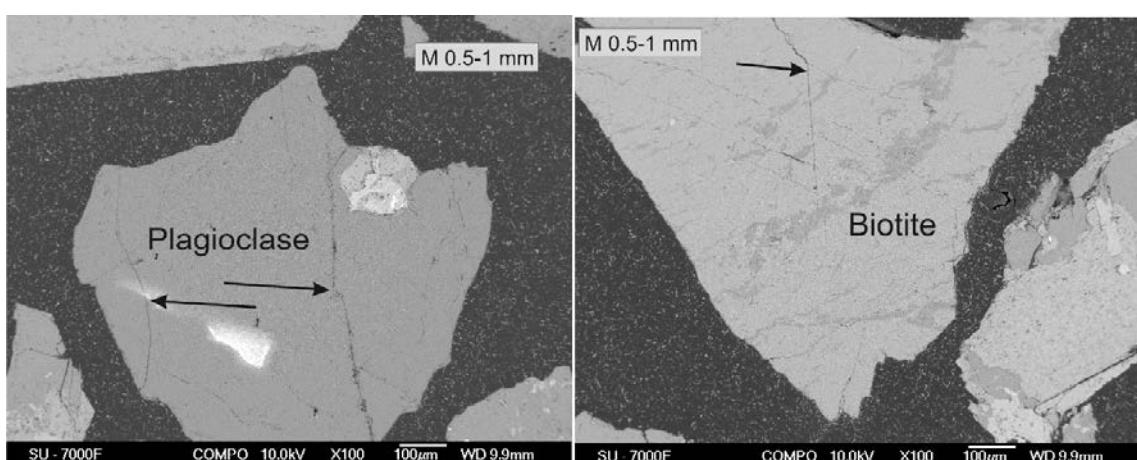

Figure 3-35. Larger cracks penetrating grains of quartz (left) and plagioclase (right).

Summary and conclusions, M sample 0.5–1.0 mm fraction

- The M 0.5–1.0 mm sample was found to be rich in pores in the approximate size range 0.1–2 μm . The pores were widely spread across the entire grains of quartz and feldspar and also appeared in biotite minerals. The occurrence of these pores were much larger compared to the 2.0–3.0 mm fraction. This may be an effect of pore-rich minerals being more prone to fragment, using mechanical crushing, than more solid ones leading to the overrepresentation of these grains in the smaller fraction. One cannot exclude the possibility that at least some of the pores have been created during the crushing since their occurrence is high also when comparing with the drill core sample. However, the poor polishing of this thin section makes the interpretation of pore occurrences very uncertain for this sample.
- In comparison with the 2.0–3.0 mm fraction the smaller grains did not seem as altered at the grain boundaries with regards to μm sized cracks. Even if it cannot be verified it is possible that, due to the larger amount of pores, fractures close to the grain boundaries have more easily been connected leading to the formation of new small grains without applying so much of a mechanical force.
- Cracks perpendicular to the orientation of biotite sheets were not found in the 0.5–1.0 mm fraction. This could be an effect of the formation of new grains with these cracks found in the 2.0–3.0 mm fraction as fresh grain boundaries. This is especially possible since these cracks should be the most obvious places for fragmentation to occur when applying a mechanical force.
- Larger fractures in quartz and feldspar crystals did not appear specifically at grain boundaries as was the case for the larger fraction. This could be merely an effect of the size of the particles since mechanical crushing is likely to lead to a larger percent of a grain being altered with decreasing particle size (André 2009).

3.3.5 HV sample, 0.5–1.0 mm fraction

The 0.5–1.0 mm HV sample was apparently quite porous in the size range of approximately 0.1–2 μm (Figure 3-36). These pores can be considered to be somewhat more common in the 0.5–1.0 mm fraction compared to the 2.0–3.0 mm, although the rather inconsistent polishing of the thin sections make straightforward comparisons of these thin sections difficult, and overall makes it difficult to distinguish whether the pores are natural pores or just uneven parts of poorly polished mineral grains. Grain boundaries tended to be altered to the same extent as the larger fraction, *i.e.* no or just a slight increase compared to the interior of the grains (Figure 3-37 and Figure 3-38). The short and narrow cracks found in the M sample in the same size fraction (Figure 3-32) were not seen for the HV sample.

For biotite, pores were detected within grains (Figure 3-37) about to the same extent as the M 0.5–1.0 mm sample (Figure 3-31) and somewhat more than for the larger HV fraction (Figure 3-28). Larger fractures were found between biotite sheets (Figure 3-39) but no spreading of the sheets close to grain boundaries was detected (Figure 3-40, cf. Figure 3-24 (M 2.0–3.0 mm) and Figure 3-27 (HV 2.0–3.0 mm)). Cracks perpendicular to the cleavage plane were almost completely absent but a few examples were found (Figure 3-39, right).

Larger fractures, in the range of tens of μm to the same size as the grains, were also found in quartz and feldspar grains and to a relatively large extent. Their occurrence and placement was about the same as for the larger fraction, *i.e.* some fractures were present mainly close to grain boundaries (Figure 3-41) but most fractures occurred in the middle of grains (Figure 3-42). Fractures seemed to have formed both randomly and along cleavage planes.

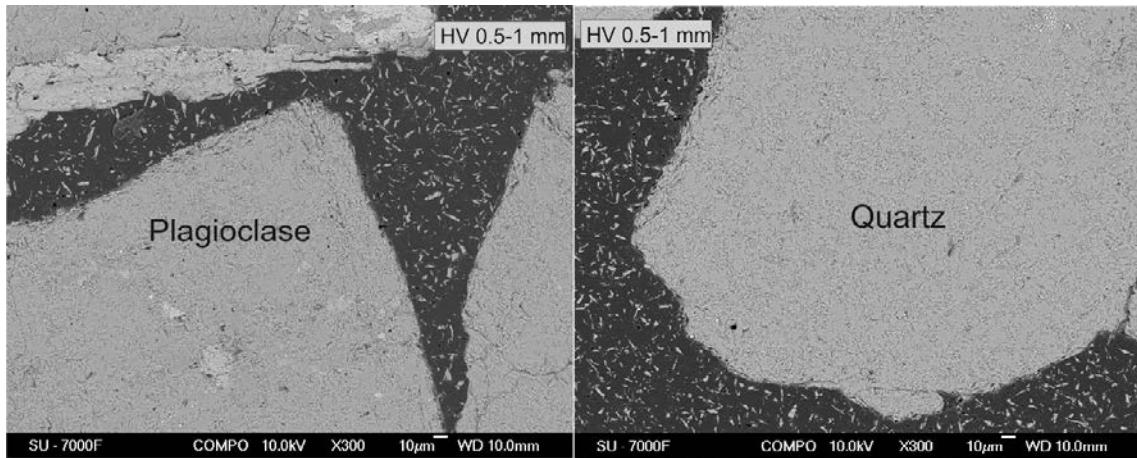

Figure 3-36. Plagioclase (left) and quartz (right). The interior of the grain is quite porous in the approximate 0.1–2 μm pore width range, however, this is mainly due to poor polishing.

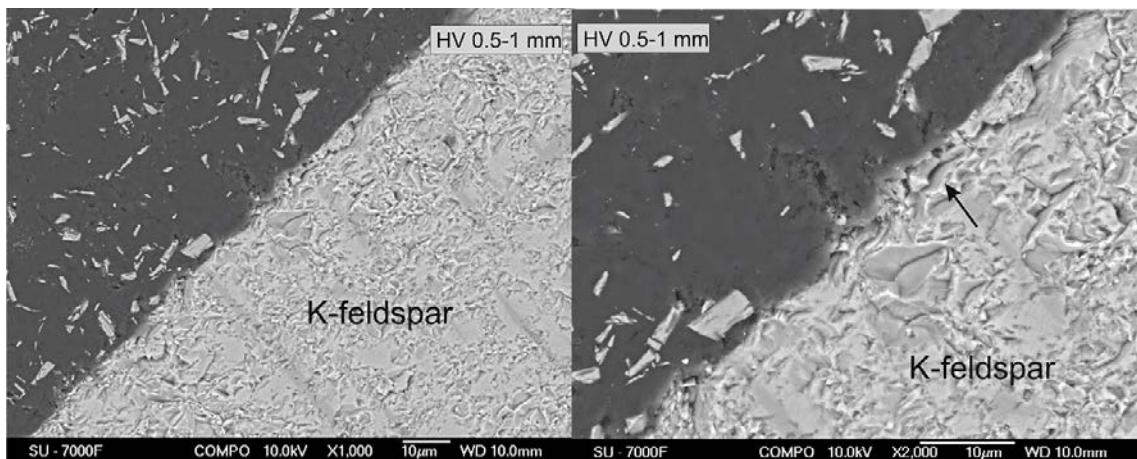

Figure 3-37. Example of a K-feldspar grain at two different magnifications. At the grain boundary there is only slightly (arrow), if any, increased alteration compared to in the interior of the grain. However, the uneven thin section surface (poor polishing), makes a thorough investigation of fracturing at the grain boundary difficult. A slightly better polished area in the image below illustrates these features better.

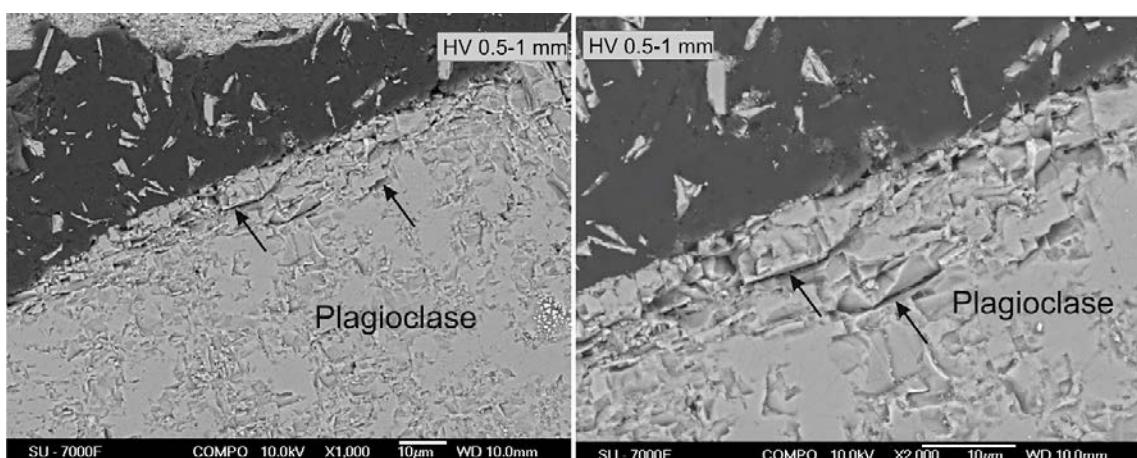

Figure 3-38. Example of a plagioclase grain with increased amount of cracks in the μm range at the grain boundary.

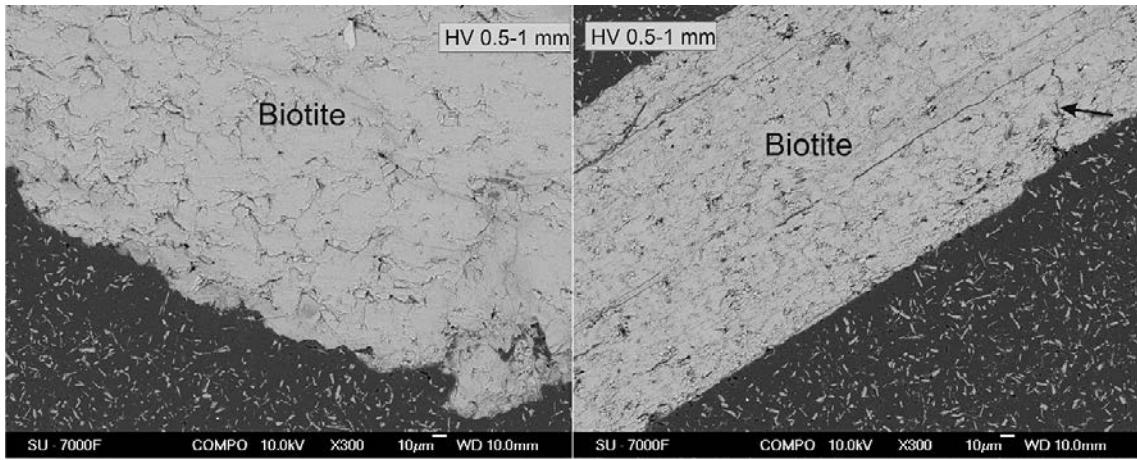

Figure 3-39. Examples of biotite grains where pores within the grains are somewhat more common compared to the larger fraction. Note the crack perpendicular to the cleavage plane on the right picture (arrow).

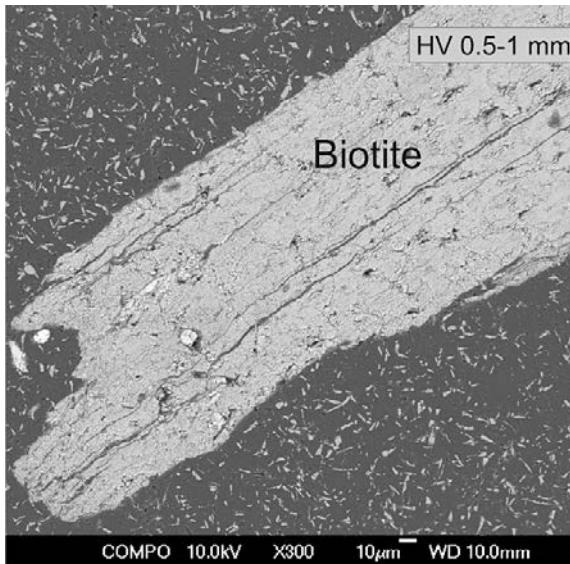

Figure 3-40. Example of fractures occurring between biotite sheets. There is no spreading of the sheets close to the grain boundary as was the case for the larger fractions of both M and HV samples.

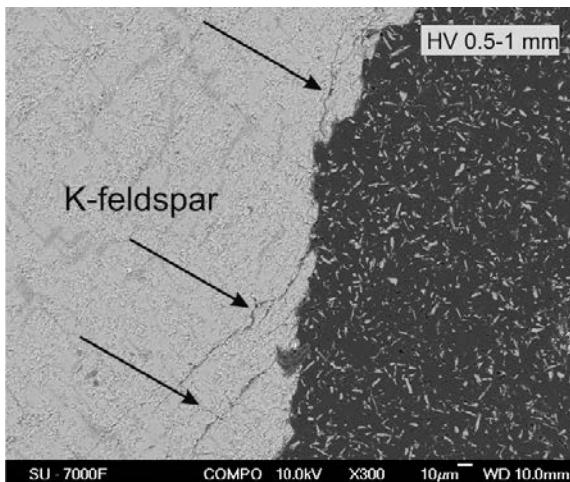

Figure 3-41. K-feldspar with larger fractures (arrows) close to the grain boundary.

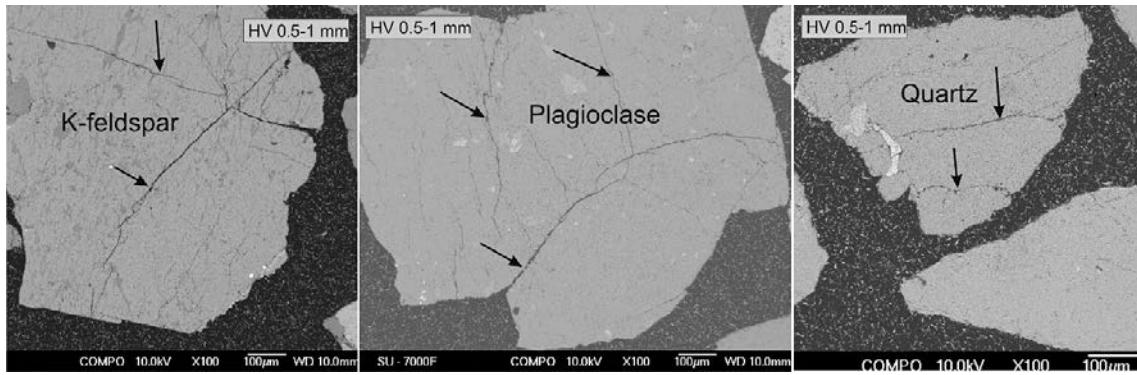

Figure 3-42. K-feldspar, plagioclase and quartz crystals with larger fractures penetrating the entire grains (arrows).

Summary and conclusions, HV sample, 0.5–1.0 mm fraction

- Although there is difficulty in comparing porosity between thin sections due to inconsistent degree of polishing, there is an indication of an increase in porosity of 0.1–2 µm pores in quartz and feldspars than in the larger fraction but it is hard to establish a certain difference.
- Cracks in the µm range close to grain boundaries and larger fractures through grains were very similar to the larger fraction. The only difference is that biotite sheet separation was found for the larger but not the smaller fraction.

3.3.6 Final conclusions from the SEM study

All crushed samples show some alteration compared to the drill core samples. Regarding pores within crystals, the M sample minerals contained small amounts of pores in the 0.1–2 µm range. These were seemingly underrepresented in the smaller fraction but due to the inconsistency in the degree of polishing of these thin sections, no certain conclusion can be drawn. The difference in micro-fracturing is thus the most reliable observation to distinguish differences between the two crushing methods and between the different fractions. In this comparison the M sample 2–3 mm had higher amount of cracks close to the grain boundaries, more sheet separation of biotite along grain-boundaries and more fractures perpendicular to cleavage planes in the interior of biotite grains than the smaller M fraction and both of the HV fractions. The HV sample (both fractions) had more fractures through large grains, or grain aggregates, than in the M sample. The two HV fractions were similar to each other, although the smaller fraction had almost no sheet separation of biotite at grain-boundaries, in contrast to the larger fraction. The HV method seems to have resulted in similar crushing-related alteration features for the different fractions compared the M fractions, and has therefore produced a more homogeneous residue. The minerals of the M sample, at least the 2–3 mm, were more affected by the crushing than the HV samples, if longer fractures through mineral grains are excluded. The M method seems to have preferentially affected mineral grains close to grain-boundaries (increased fracturing), whereas the HV method to a larger extent fragmented grains at a larger scale, across whole grains and aggregates of grains. Furthermore, the M method seems to have affected the larger crystals more than the smaller ones, especially biotite, which showed more intense fracturing and alteration in the larger fraction.

3.4 Optical microscope

All fractions were examined using optical microscope, see Figure 3-43. The most evident difference between the two differently crushed rocks was the shape of the grains. The mechanically crushed grains were more angular than the grains crushed with high voltage that seemed more rounded. This was observed for the large fractions and even more so in the smaller fractions (0.25–0.50 and <0.25 mm) where many of the mechanically crushed grains had very sharp edges and rather elongated shapes. Most of these grains were observed to be feldspars, probably fragmented along their natural crystal lattice.

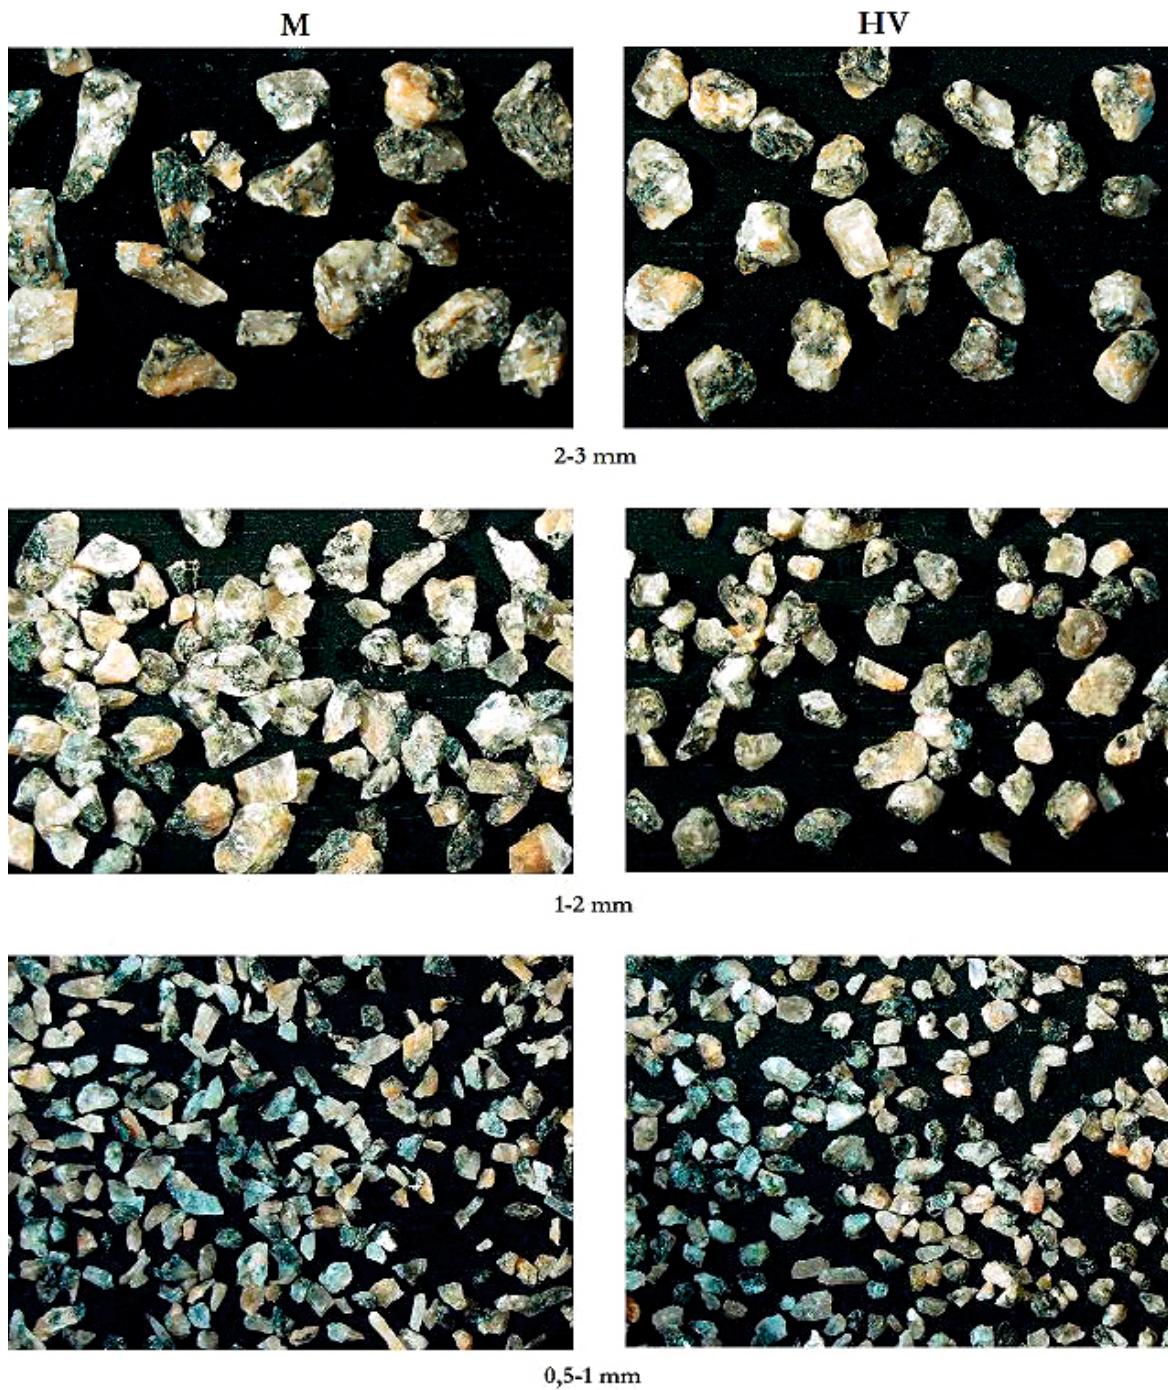

Figure 3-43. Example photos (both above and on the next page) of the different size fractions observed in the optical microscope (M to the left and HV to the right). The same magnification was used for both samples when comparing the size fractions. Width of photos is about 2 cm, except <0.25 mm, which is 2 mm wide.

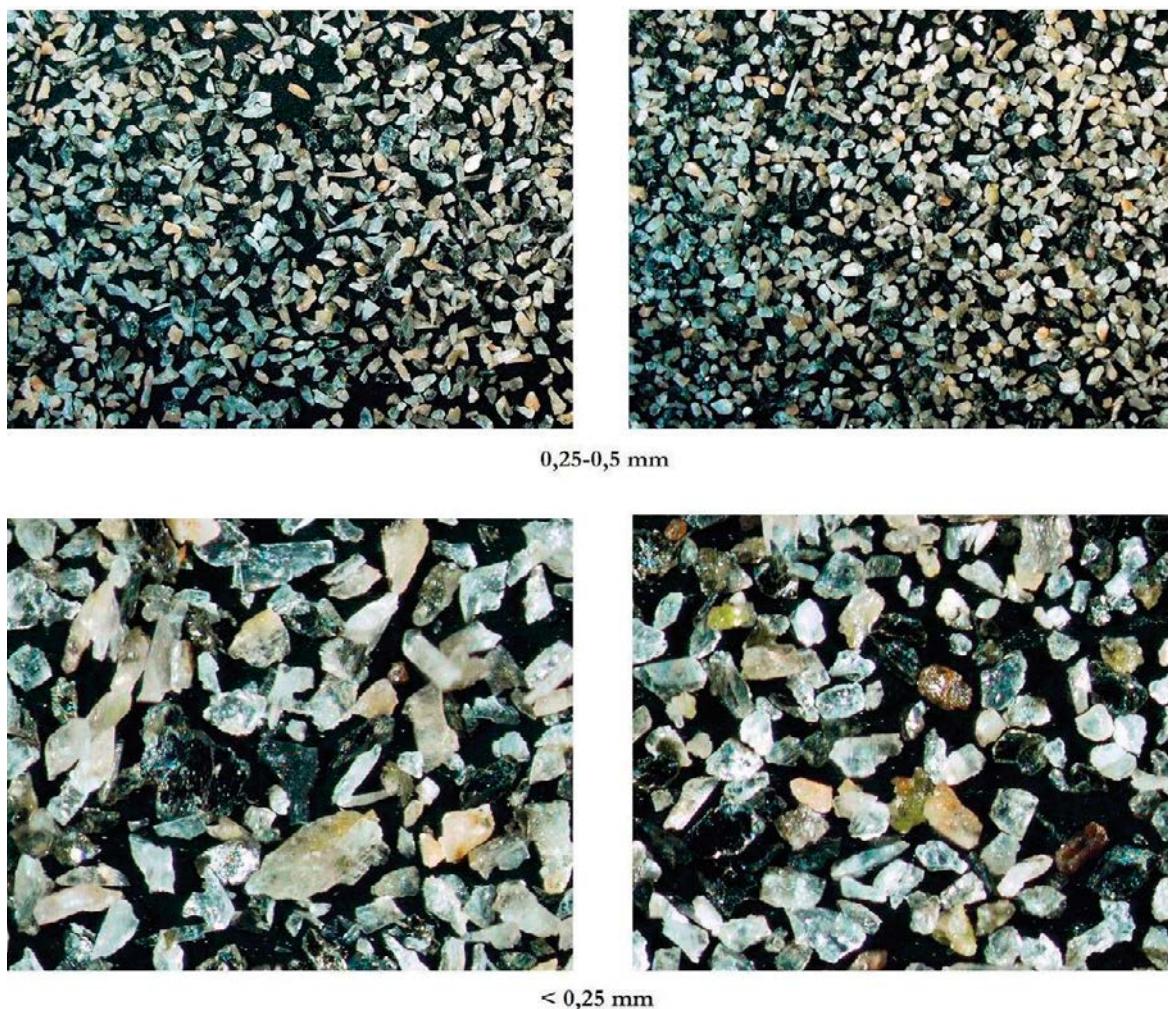

Figure 3-43. (Continued).

A large part of the M sample grains in the three smallest fractions were observed to be in the form of thin flat flakes. No such equivalent was found for the HV samples in the same size fractions. Another observation was that the size distribution seemed more even for the HV samples compared to the M samples for all fractions.

3.5 Reducing capacity

Measurements of the oxygen gas content in the flasks were carried out frequently during a period of 217 days to study the reducing capacity of the rock material (Figure 3-44 and Appendix A1.1). Because the starting concentration of O₂ differed somewhat in the six samples the results are presented as % change in O₂ (i.e. (O₂, time T/O₂, start) – 1), although it should be noted that this approach did not take into account any effect of the specific O₂-consumption rates resulting from different starting concentrations of O₂. The maximum positive change of the control samples were +5.1% and the negative change –5.9%. Changes within this range (marked with grey dotted lines in Figure 3-44) can thus not be considered to have happened due to oxygen consumption in the samples containing rock material.

Except for a couple of anomalously high or low values, the oxygen contents of the gas phase showed a steady decreasing trend for the flasks containing rock material.

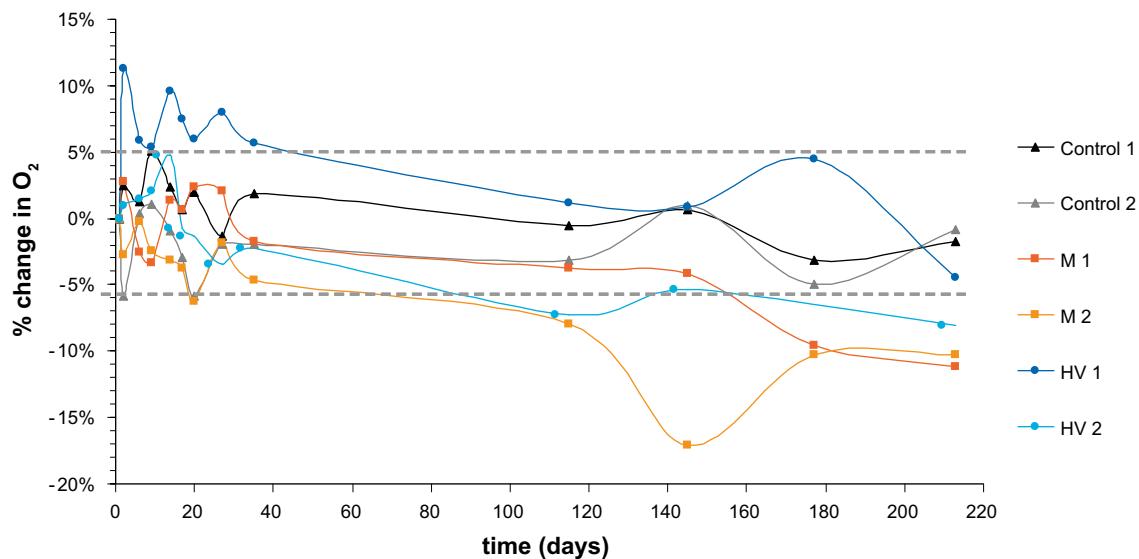

Figure 3-44. Change in oxygen gas concentration in relation to the starting value over the 217 days measurement period. The grey dotted lines show the maximum range where variations have been detected in the control samples.

The HV 1 sample showed a large increase in $[O_2]$ during the first 35 days of the experiment. For the remaining of the monitoring period, the HV 1 sample experienced a net decrease in oxygen concentration, but due to the initial increase, the final value is within the estimated error equal to that of the control samples. The HV 2 sample has a final value that can be considered to show a true decrease in oxygen concentration (-8% , somewhat below the precision of the blank samples).

The two M samples show a greater decrease in oxygen during the last period of the experiment and both samples have experienced a larger consumption of oxygen at the end of the study ($(10 \pm 5)\%$ and $(11 \pm 5)\%$) than the HV 2 sample, although within the estimated uncertainty of the method.

For the HV 2 sample a decrease of 8% in the oxygen content after 217 days would correspond to an oxygen consumption rate of about $1.5 \cdot 10^{-11}$ mol/(kg rock) (in total $2.8 \cdot 10^{-4}$ mol consumed O_2 per kg rock) for the HV sample, and for the M sample corresponding values would be $2 \cdot 10^{-11}$ mol/(kg rock) (in total $3.7 \cdot 10^{-4}$ mol consumed O_2 per kg rock) (based on the average O_2 decrease of the two samples). Using the BET data (see Table 3-3) this corresponds to $8.3 \cdot 10^{-14}$ mol/(m^2 s) and $9.4 \cdot 10^{-14}$ mol/(m^2 s) for the HV and M samples, respectively (total mol consumed O_2 per m^2 surface area being $1.56 \cdot 10^{-6}$ and $1.77 \cdot 10^{-6}$, respectively), i.e. slightly larger oxygen consumption per m^2 surface area for the M sample (although it should be noted that the differences in O_2 consumption between the samples were within the estimated $\pm 5\%$ uncertainty). Biotite makes up about 17 vol.% in the HV sample and 15.1 vol.% in the M sample, reported in the Appendix (Table A-12), and expecting similar densities for all minerals, the oxygen consumption rate is about $9 \cdot 10^{-11}$ mol/(kg-biotite s) for the HV sample and $1.4 \cdot 10^{-10}$ in the M sample (by dividing the oxygen consumption rate per kg rock with the portion of biotite in the rock).

Table 3-3 shows, as expected, general decreasing BET areas with increasing grain size for both the HV and the M samples, in accordance with André (2009). However, the HV 2–3 mm sample and the M 1.0–2.0 mm do not follow this trend. Due to the high BET surface area in the largest HV fraction, there is a large difference between the HV and M sample when comparing the difference of the largest and smallest fractions, which have smallest and largest surface area, respectively, in the M sample.

Table 3-3. BET area (m^2/g) for the HV and M samples. Duplicate measurements were made for the 0.50–1.0 mm samples.

Size fraction (mm)	BET (m^2/g) for HV samples	BET (m^2/g) for M samples
0.25–0.50	0.2834	0.3369
0.50–1.0 (1)	0.2159	0.1964
0.50–1.0 (2)	0.2047	0.1949
1.0–2.0	0.1840	0.2167
2.0–3.0	0.2325	0.1390

3.6 Sorption capacity and weathering tendency

The study of the sorption capacity did not go as planned due to substantial release of strontium from the rock material. It was thought that by monitoring the weathering of Sr using blank samples with strontium-free synthetic groundwater these values could be deducted from the Sr concentration in the sorption samples. However, it turned out that the contribution of Sr from weathering was so large that it affected the entire sorption system. In this section actual concentrations in the solution and modified concentrations, where blank concentrations are subtracted, are presented. It should be noted that the modified concentrations probably do not fully account for the actual sorption mechanisms, as these are dependent on the concentration used in the experiment.

3.6.1 Distribution ratio, R_d

Adsorption

As can be seen in Figure 3-45, $\text{Sr}(\text{aq})$ only experienced the expected decrease in concentration initially, during the first seven hours. Thereafter, from the sampling performed 24 hours after the experiment start, the actual concentration increased due to the contribution from leaching. Even after deducting the $[\text{Sr}]$ values from the blank samples it was obvious that the leached strontium had affected the entire sorption system to such an extent that concentrations were still increasing after 24 hours. Due to this, plots of the distribution ratio are not presented.

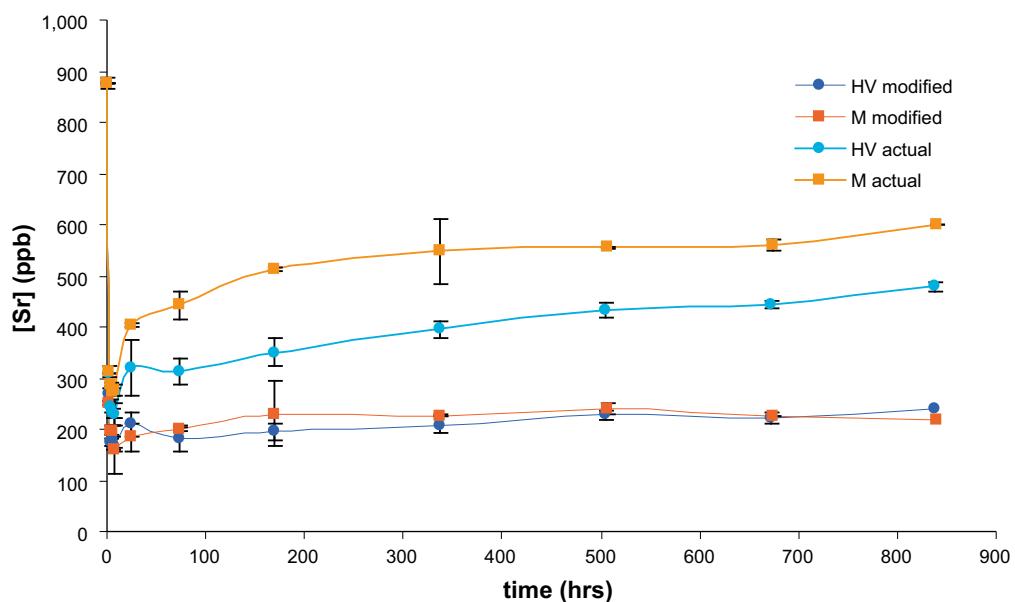

Figure 3-45. Strontium concentration in solution over time during the adsorption phase. The values from the blank samples have been deducted from the actual concentration for the samples named HV and M modified. All values are mean values from double samples. Error bars show the minimum and maximum values.

The initial rapid decrease in strontium concentration is most likely attributable to sorption on outer surfaces (Park and Hahn 1999). The modified concentrations for both samples show small differences during this initial time period but due to the dominating contribution of Sr from leaching for the remaining time period of the experiment it is hard to draw any conclusions regarding sorptive properties of the samples, and from the blank measurements (Figure 3-46) it is obvious that equilibrium is never achieved which further hinders useful interpretations. Furthermore, pH measurements indicate that the pH was not constant throughout the experiments, at least not within the first approximately 100 hours (Figure 3-50 and Figure 3-51), also indicative of disequilibrium. However, there is a significant difference in Sr concentration over time between the two samples, see Figure 3-45. The data shows that more strontium leached from the M sample, possibly due to relatively high fragmentation (indicatively larger surface area and/or higher reactivity of the surfaces) of Sr-bearing mica and plagioclase (probably also epidote). In the blank samples the concentration was higher in the M sample throughout the entire adsorption phase (Figure 3-46).

Desorption

During the desorption phase the initial plan was to perform a sequential extraction with synthetic groundwater (SWG), CaCl_2 (0.5 M) and KCl (0.5 M) to study the binding mechanism and potential differences in behaviour between the two differently crushed rock samples. However, due to contamination of Sr in the CaCl_2 solution only values from the desorption in SGW will be presented. The Sr concentrations during desorption in SGW are presented in Figure 3-47.

The actual [Sr] differed between the HV and M sample. However, after deducting the leached strontium (from the blank samples) there was no significant difference (Figure 3-47). The total desorbed amount was 87 ppm for HV and 85 ppm for the M sample. It is not possible to fully determine how much Sr that adsorbed to the rock due to leaching but based on the initial seven hours of the adsorption phase one can say that it was at least 708 ppm for the HV sample and 716 ppm for M. This means that about 12% of the initially adsorbed Sr has desorbed in SGW for both samples. This is consistent with earlier studies where 10% of adsorbed strontium desorbed in groundwater conditions (Park and Hahn 1999).

There was less difference between the blank samples compared to the adsorption phase but more Sr had leached from the M sample even if the difference was not significant at all times, see Figure 3-48.

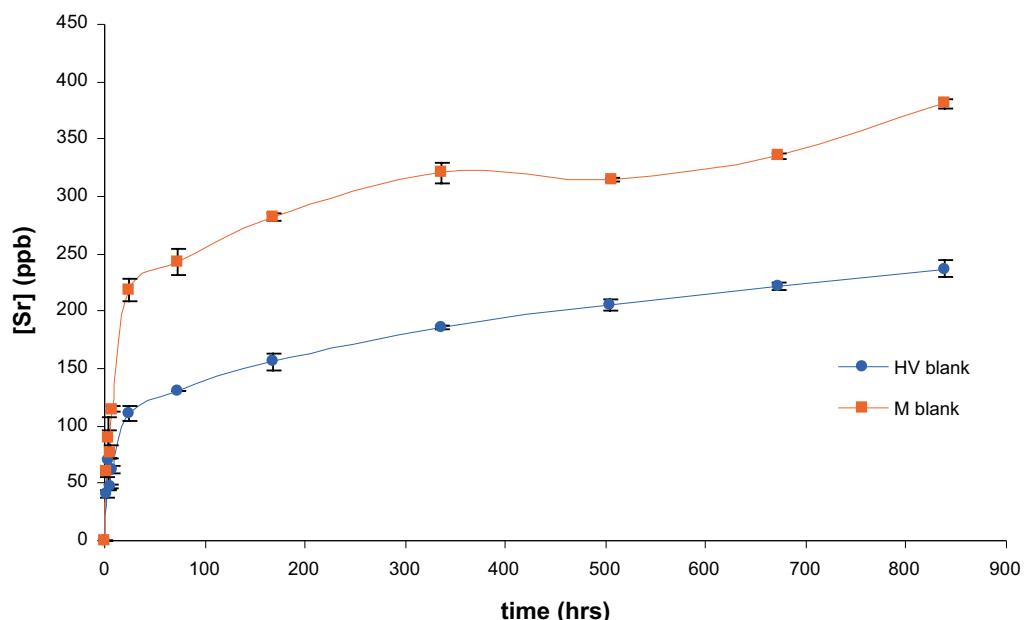

Figure 3-46. Mean concentrations of Sr in the blank samples during the adsorption phase. Error bars show the maximum and minimum values.

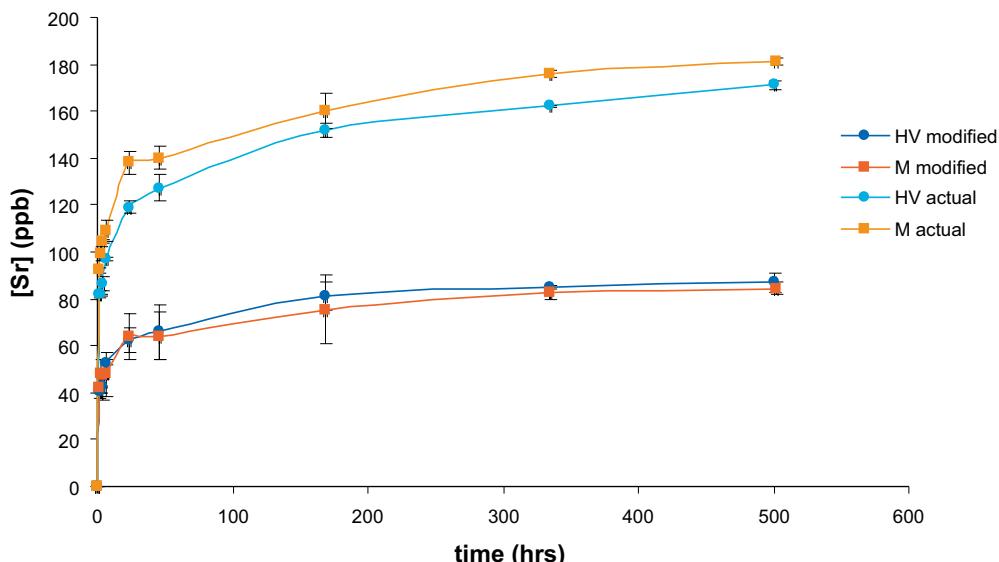

Figure 3-47. Concentration of strontium in the solution over time during desorption. The values from the blank samples have been deducted from the actual concentration for the samples named HV and M modified. All values are mean values of duplicate samples. Error bars show the minimum and maximum values measured.

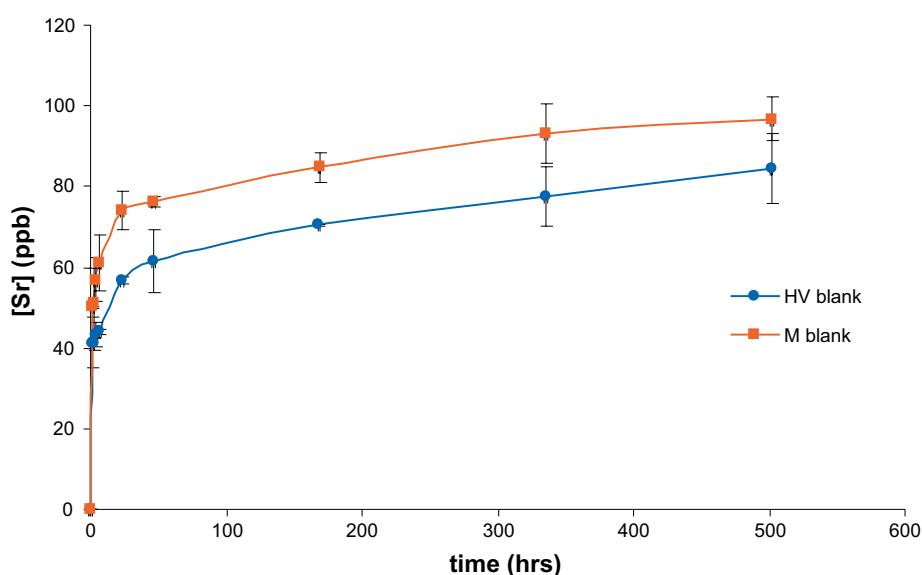

Figure 3-48. Mean concentrations of Sr in the blank samples during the desorption phase. Error bars show the maximum and minimum values. HV and M stand for high-voltage and mechanical crushing, respectively.

Because the concentrations increased with time as expected the distribution ratio, R_d , was plotted, see Figure 3-49. The data shows that there were no significant differences between the two samples during desorption. However, because leaching accounted for about half of all Sr released to solution (53% for M, 49% for HV) it is very likely that this contribution had a large effect on the sorption system and the R_d plot should therefore be interpreted with caution.

3.6.2 Isotherms

Figure 3-52 shows the percentage of the initial Sr that had adsorbed after 35 days and Figure 3-53 presents the percentage that has desorbed of the initially adsorbed strontium (corrected using a mean value of two blank measurements, which further increases the uncertainty of these samples, e.g. the M sample blank varied by >10%). The experimental time (35 days) was estimated to be sufficient from the results of the adsorption and desorption experiments described in the previous two sections.

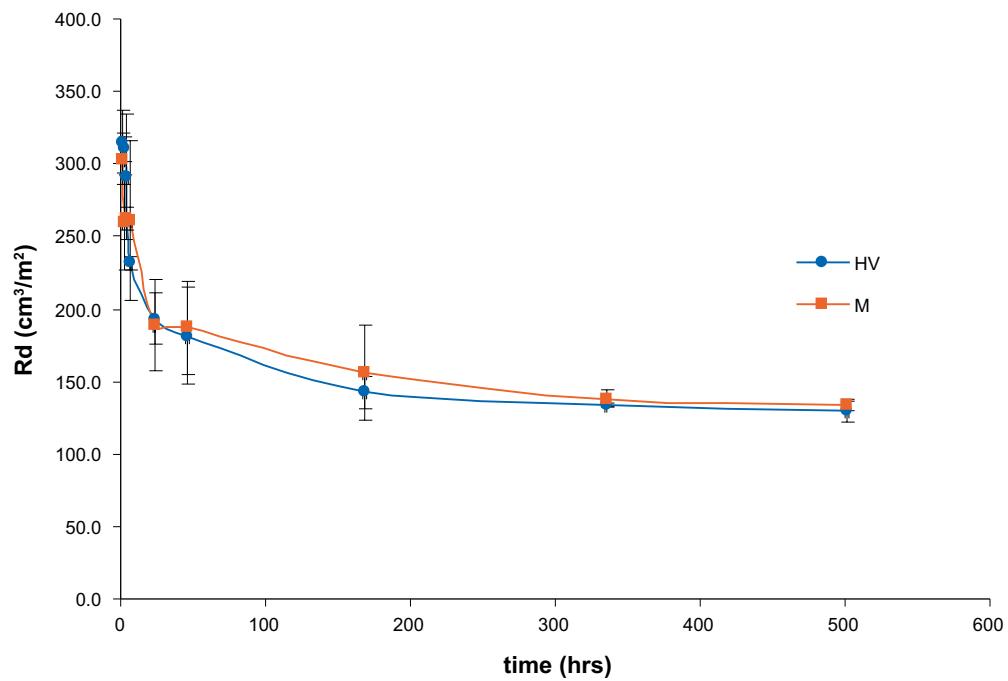

Figure 3-49. R_d values during the desorption phase. Error bars show the maximum and minimum values for the double samples.

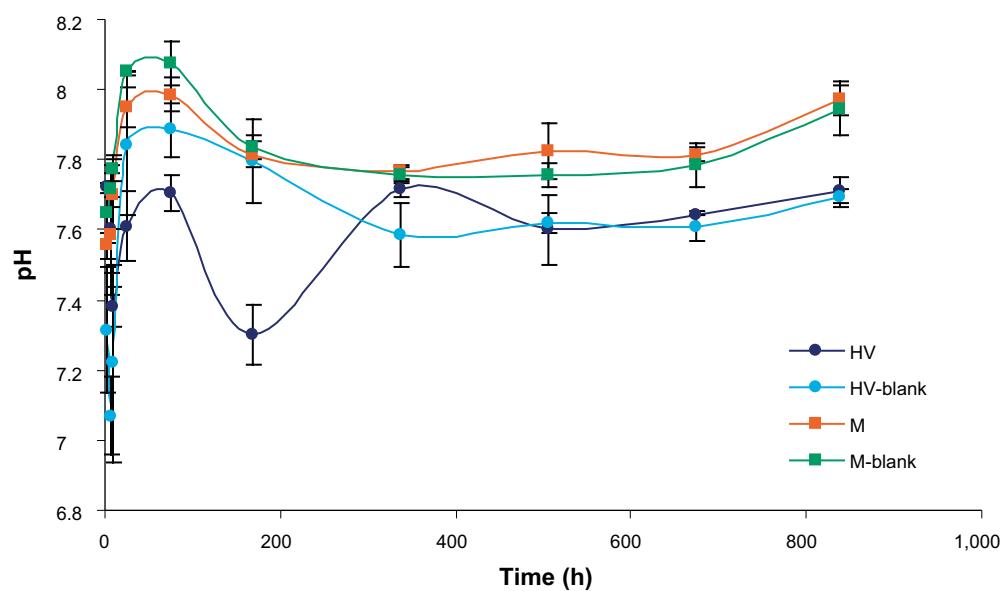

Figure 3-50. Average pH values ($n=2$) during the sorption experiment. Only values measured from 3 hours onwards are plotted; the initial pH values (8.2) have been excluded from the diagram. Error bars show the standard deviation for the double samples.

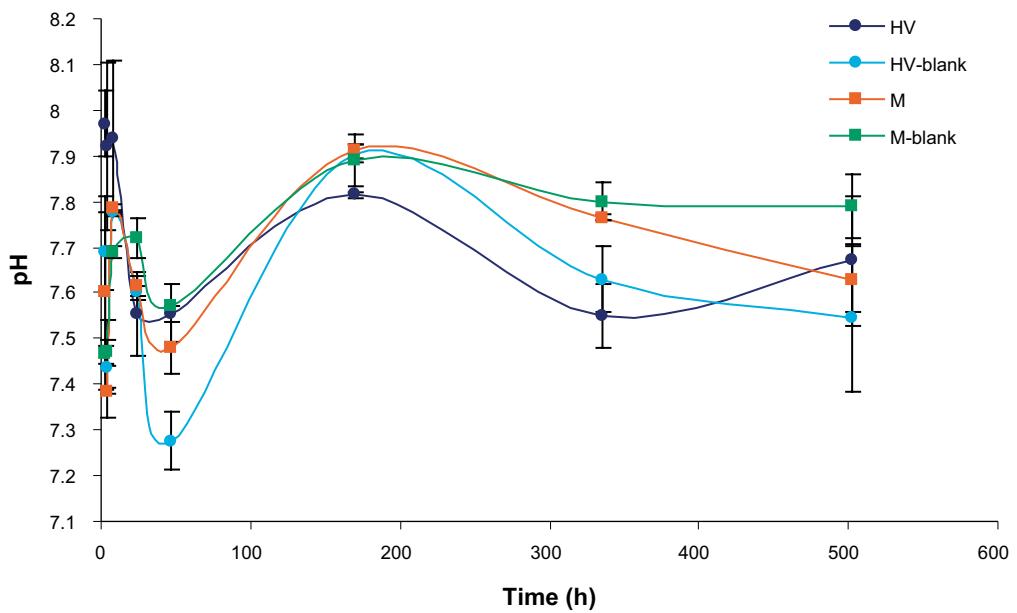

Figure 3-51. Average pH values ($n=2$) during the desorption experiment. Error bars show the standard deviation for the double samples.

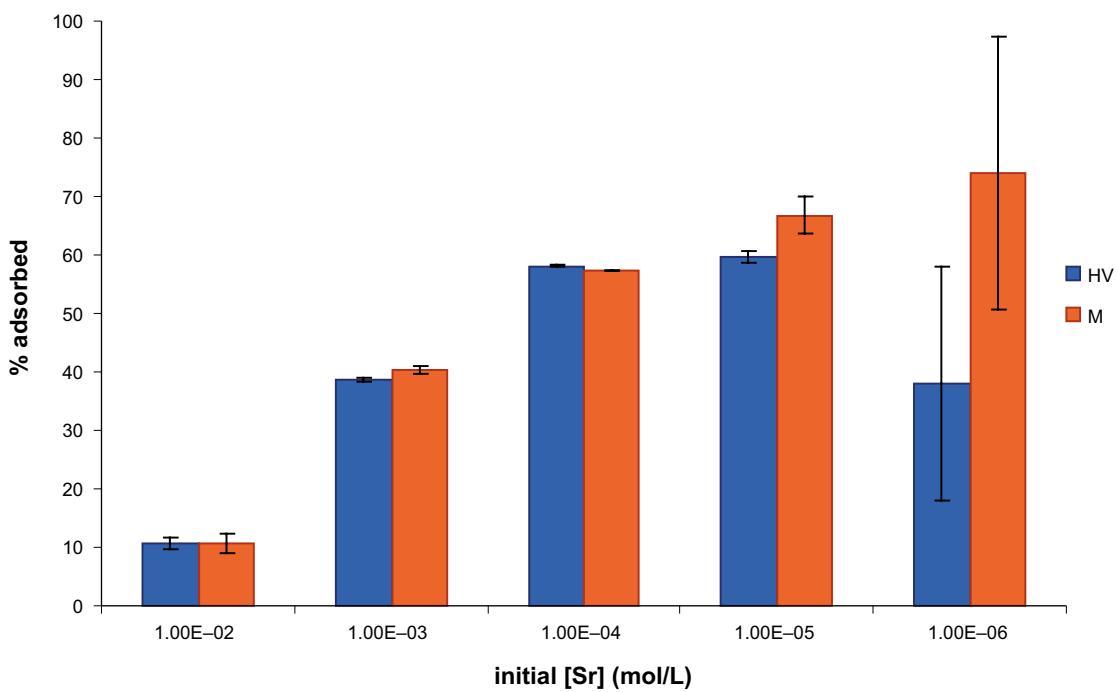

Figure 3-52. % adsorbed strontium of the initially added. Error bars show the minimum and maximum values of the duplicate samples.

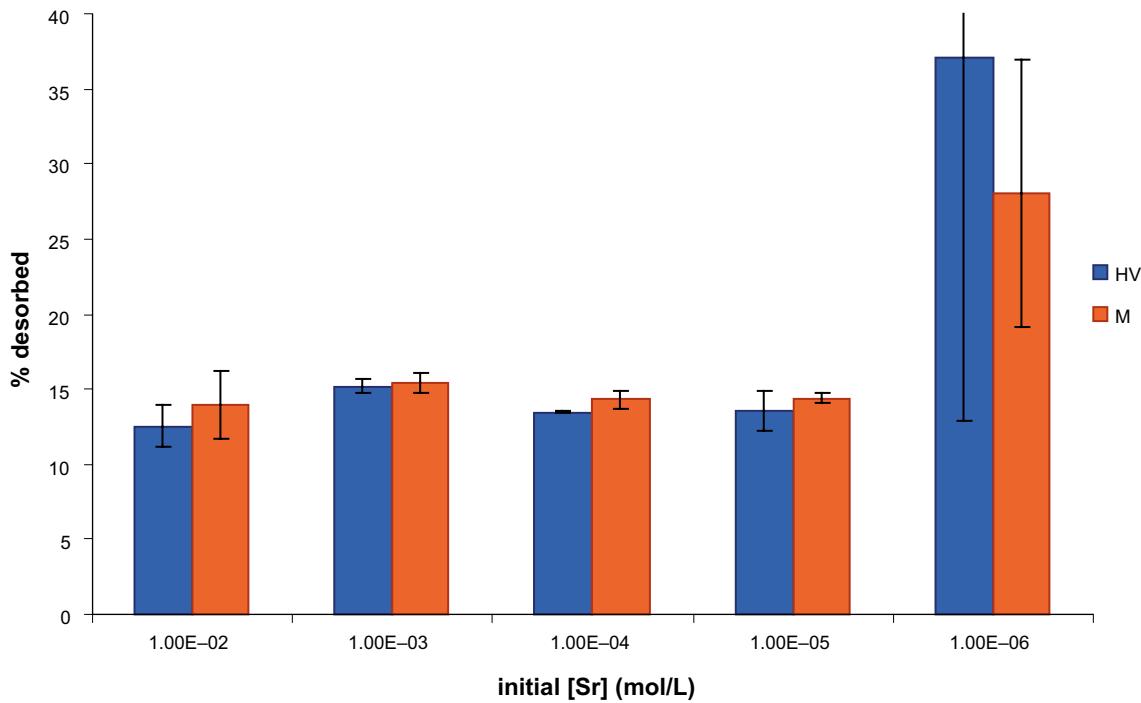

Figure 3-53. % desorbed strontium of the initially adsorbed. Error bars show the minimum and maximum values of the duplicate samples.

The samples prepared for the sorption isotherms were of course also affected by the leaching of strontium. Due to this large addition the two lowest concentrations have been removed when plotting the isotherms in Figure 3-54. Although there are large uncertainties, the percentage desorbed Sr was generally in the range of 13–15% for HV and 14–15% for M (Figure 3-53) which is not very far from the reported 10% that is expected to desorb in groundwater conditions (Park and Hahn 1999).

Sorption of strontium is commonly reported not to be dependent on strontium concentration. This gives rise to a linear isotherm which is expected for ion exchange. Because ion exchange has been found to be the major sorption process for strontium the data were plotted according to the linearised Freundlich equation:

$$\log q = n \cdot \log C + \log K \quad (\text{Equation 3-1})$$

where q is the sorption density, C the concentration of the sorbate in solution, K is the sorption density under standard conditions and n is a units-less constant describing the binding strength of the sorption sites (note the different n for sorption and desorption). The unit for q , C and K is mg/m^2 .

If the sorption is completely reversible then $n_{\text{desorption}}/n_{\text{adsorption}} = 1$ and $K_{\text{desorption}}/K_{\text{adsorption}} = 1$ and this was clearly not the case for the samples in this study, see Figure 3-54, Table 3-4 and Table 3-5 where data from the duplicate samples is presented. One cannot exclude the possibility that leaching also has affected the 10^{-4} M samples even if the leached amount only accounted for 5.3 and 6.6% for the HV and M samples respectively during adsorption. For the desorption phase the corresponding values were 8.7% (HV) and 10.2% (M). However, even if the 10^{-4} M samples would be removed from the isotherm graph the equations for adsorption and desorption would still differ. The most likely explanation is that pH differed in the adsorption and desorption solutions because the formation of SrCO_3 was avoided during adsorption only by adjusting to pH~6. The SGW used during desorption had a pH of approximately 8. pH impacts sorption processes through protonation or deprotonation of functional groups which affects the surface charge (Friedman et al. 1972). pH dropped to about 7.2 ± 0.1 during the adsorption phase and was 7.5 ± 0.1 at the end of the desorption phase, as measured after 35 days (A1.8 in Appendix 1). However, no significant difference between the two differently crushed samples can be found from the isotherm plot leading to the conclusion that, under this experimental set-up, there was no difference in the sorption capacity for the two samples.

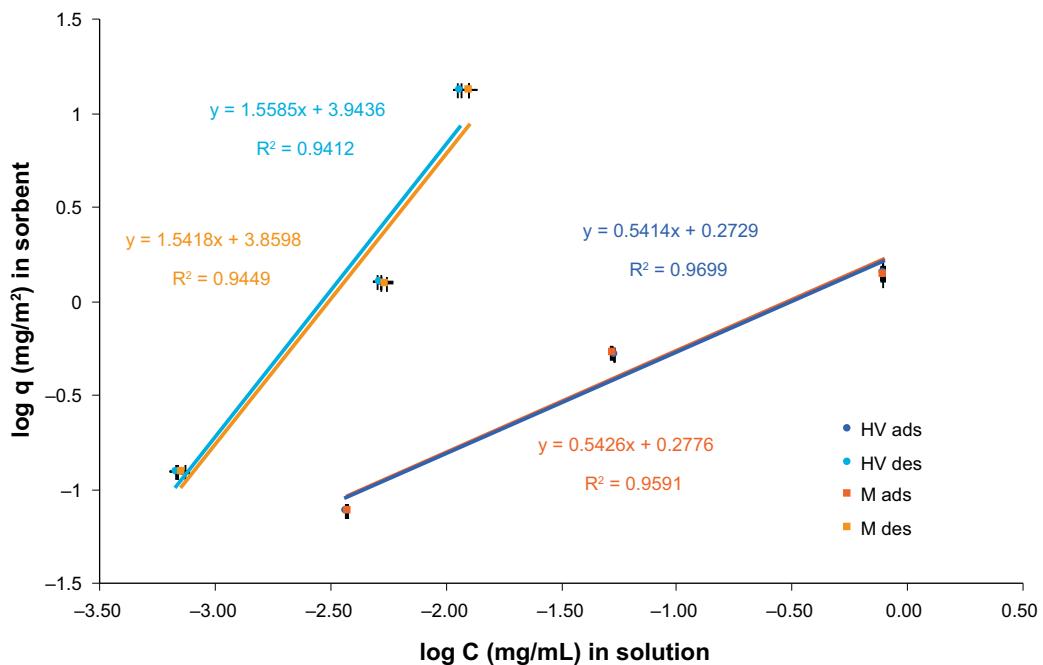

Figure 3-54. Freundlich isotherms for both adsorption and desorption. The data is mean values from the duplicate samples. The weathering contribution to [Sr] has been deducted using values from the blank samples. Only the data points corresponding to the initial Sr concentrations of 10^{-4} , 10^{-5} and 10^{-6} M are shown here.

Table 3-4. Values of K (intercept) and n (slope) from the isotherm plot for the HV double samples.

Sample	n _{adsorption}	K _{adsorption}	n _{desorption}	K _{desorption}	n _{des/n_{ads}}	K _{des/K_{ads}}
HV1	0.5245	0.2350	1.550	3.914	2.955	16.66
HV2	0.5583	0.3109	1.567	3.973	2.807	12.78
Mean	0.5414	0.273	1.559	3.944	2.881	14.72
±	0.0169	0.038	0.009	0.030	0.074	1.94

Table 3-5. Values of K (intercept) and n (slope) from the isotherm plot for the M double samples.

Sample	n _{adsorption}	K _{adsorption}	n _{desorption}	K _{desorption}	n _{des/n_{ads}}	K _{des/K_{ads}}
M1	0.5102	0.2087	1.563	3.893	3.064	18.65
M2	0.5752	0.3471	1.521	3.827	2.644	11.03
Mean	0.5427	0.2779	1.542	3.860	2.854	14.84
±	0.0325	0.0692	0.021	0.033	0.210	3.81

3.6.3 Iron, aluminium and magnesium

The concentration of the metals Al, Fe and Mg varied over time for all samples during both adsorption and desorption. The bottles containing the samples were shaken prior to each sampling to even out potential concentration gradients. At several occasions, small particles of biotite were detected in the solution after shaking and it is very likely that some of these particles were taken up along with the extracted samples and dissolved when the samples were acidified. This would explain the variation in concentrations and the strong correlation between the three metals because they would all originate mainly from biotite. Due to this probable strong influence from residual biotite, the results of adsorption and desorption are not presented in detail but only as raw data in the Appendix.

3.6.4 Conclusions

Due to the substantial release of strontium from the rock material the determination of the distribution ratio and isotherms did not go as planned. However, from the blank analyses it is indicated that more strontium has leached from the M samples. This implies that the mechanically crushed rock has a larger area of reactive surfaces or higher reactivity of the surfaces.

4 Summary and conclusions

Several of the sub-investigations presented in this report can be regarded as being of high scientific quality (SEM and microscope investigations coupled with analyses of chemical composition, as well as pore volume measurements; pore size distribution and surface area). In contrast, the investigations of sorption capacity and weathering tendency suffered from larger experimental problems and uncertainties and the implications of these results are thus more limited. In addition, the material used for the different methods (high-voltage and mechanical crushing) differed slightly in chemical and mineralogical composition, which probably has influenced the results to a variable, and generally unquantifiable, degree. The results of the mineralogical and pore size distribution can be summarized as follows:

- Studies with optical microscope showed that angular feldspar surfaces occurred more frequently in the M samples compared with the HV samples. The SEM investigations showed that all crushed samples had some alteration compared to the drill core samples. No certain conclusions regarding intra-crystalline pores could generally be drawn for the different materials and fractions due to inconsistency in the degree of thin section polishing. There were, however, distinguishable differences in the degree and characteristics of micro-fracturing. The minerals of the M sample, at least the 2–3 mm, were more affected by the crushing than the HV samples, if longer fractures through mineral grains are excluded. The M method seems to preferentially have affected mineral grains close to grain-boundaries (increased fracturing), whereas the HV method to a larger extent had fragmented grains at a larger scale, across whole grains and aggregates of grains. Furthermore, the M method seems to have affected the larger crystals more than the smaller ones, especially regarding biotite, which showed more intense fracturing and alteration in the larger fraction. The two HV fractions were generally more similar to each other than the M fractions.
- BET areas generally decreased with increasing grain size for both the HV and the M samples, although the HV 2–3 mm sample did not follow this trend. The pore size distribution curves show that in the range of 90 to 800 Å HV samples from all size fractions measured have larger quantities of pores compared to the M samples. This indicates either that the HV crushing has increased the amount of pores in this size range or that there were differences in pore occurrence in the original rock material. The PSD was quite similar between the larger size fractions while the smallest fraction measured, 0.25–0.50 mm showed a positive deviation for both crushing methods. For the HV samples the total surface area of pores >800 Å decreased with increased particle size while the surface area for smaller pores (15–800 Å) increased slightly. The M samples show a general decrease in both 15–800 Å and <800 Å pores from the 0.25–0.50 Å to the two larger fractions. The 2.0–3.0 mm fraction deviated for both HV and M samples, perhaps due to dominance of resistant K-feldspar phenocrysts. Because the surface area for both pore width groups differed for both samples between the grain sizes, alteration and/or selectivity is likely to have occurred during both crushing procedures.

Conclusions of the investigations of oxygen consumption and sorption capacity and weathering tendency are limited as stated above, but include:

- The 217 days long monitoring of oxygen consumption showed trends of decreasing concentrations for both rock samples. Although, indication of largest decrease for the mechanically crushed sample was observed (M: –11% compared to HV: –8%), it was within the estimated uncertainty ±5% of the method.
- The sorption experiment did not proceed as planned due to massive amounts of strontium leaching from the rock material which affected the entire sorption system. It was indicated that more strontium leached from the mechanically crushed rock, implying larger area of reactive surfaces or higher reactivity of the surfaces of this material.

In conclusion, the observed slightly greater oxygen consumption and angular feldspar surfaces indicate that mechanical crushing has created larger area of reactive surfaces or higher reactivity of the surfaces. None of the crushing methods have created grains that show similar pore size distributions over the entire spectra of grain sizes. This indicates that both crushing methods have led to alteration of the rock material making none of them representative for intact bedrock and, hence, none of the crushing methods have produced completely unaffected grains. Even so, SEM investigations showed

that the high voltage crushing has affected the crushed grains less than the mechanical crushing, and also produced grains that are more similar between different size fractions. Therefore, the general conclusion is that high voltage crushing method creates a material that is more representative for intact bedrock, although there are large uncertainties related to some of the methods and to the slight difference in the composition of the starting material.

5 Acknowledgements

The authors want to acknowledge Prof. Mats Johnsson at Stockholm University for all guidance and moral support during the project as well as Prof. Alasdair Skelton (Stockholm University) for assisting with mineral identification and rock classification, Kjell Jansson, Stockholm University for help while using the SEM and also to Eva Björkman, Stockholm University for creative input.

This project was funded by the Swedish Nuclear Fuel and Waste Management Co. (SKB).

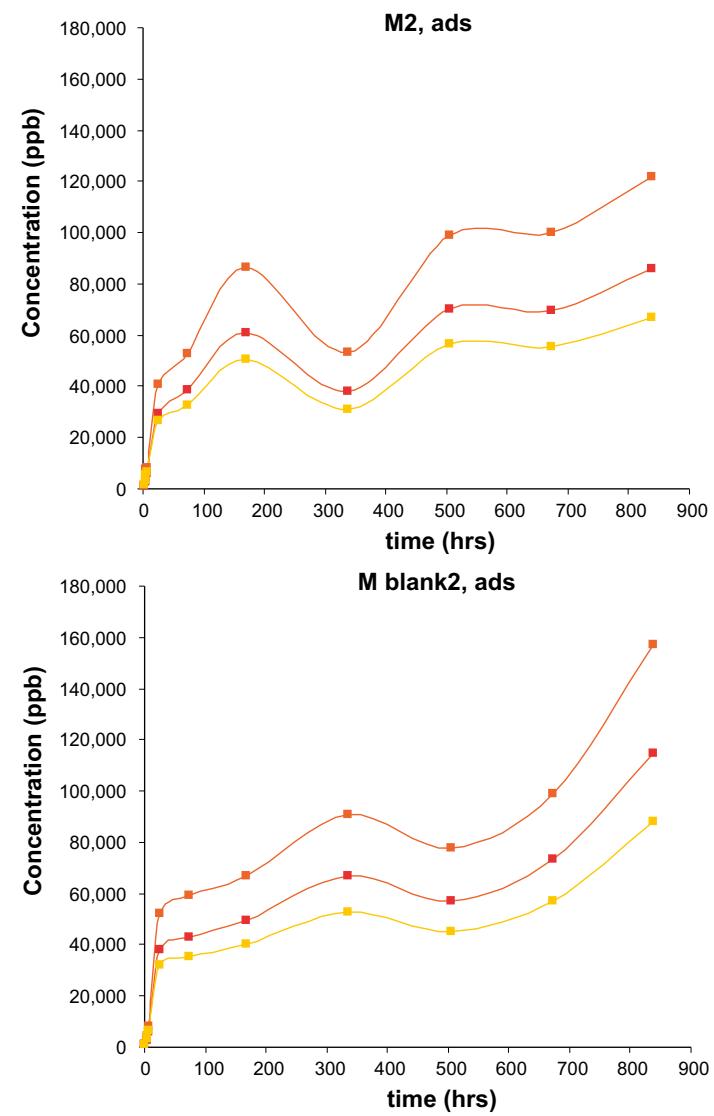

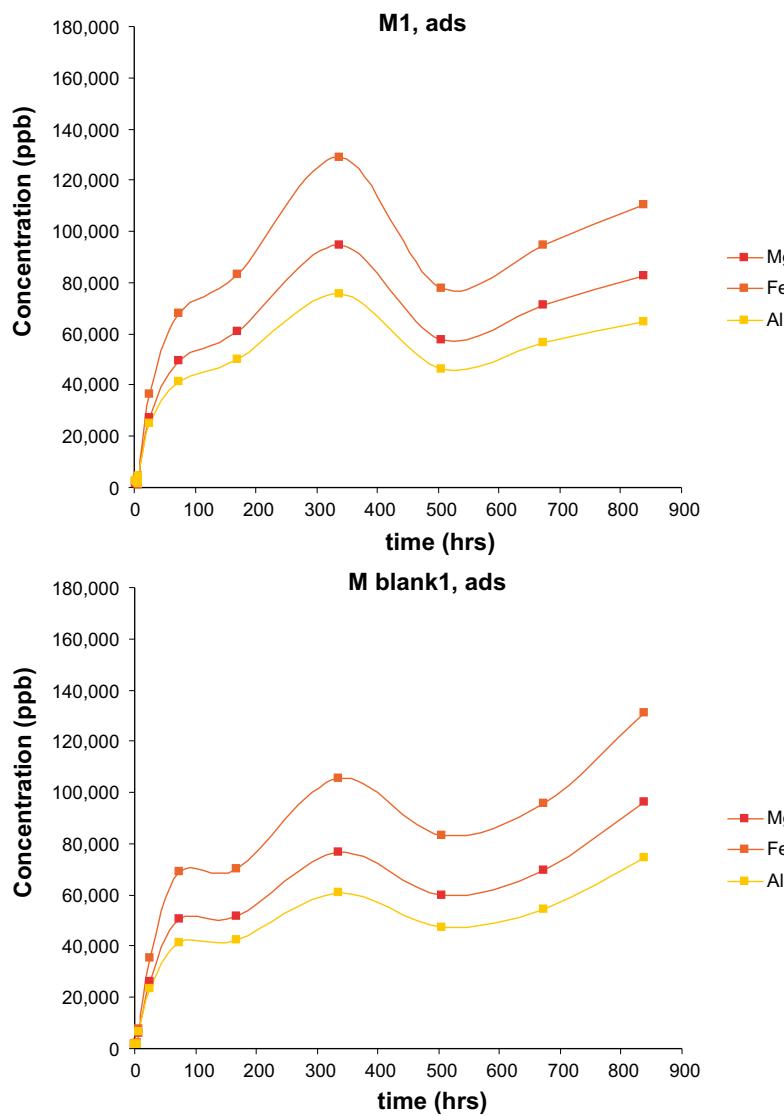

Figure A1-2. (Continued).

A1.2 Mineral compositions

Table A1-12. Determination of mineral composition by point counting using thin sections of drill core samples and classification of rock type. Points that were counted as “not valid” were in grain boundaries and not included in the % distribution between minerals. Points where the mineral could not be identified (marked “unknown”) were included in all calculations. Primes (in the lower table) are calculated as in the following example: $Q' = 100 \cdot Q / (Q + P + A + F)$.

Point counting from thin sections					% distribution						
Mineral	M 1	M 2	HV 1	HV 2	Mineral	M1	M2	M mean	HV1	HV2	HV mean

Summary Report

Surface Area

Single point surface area at p/p^{*} = 0.306574610: 0.2791 m²/g

BET Surface Area: 0.2834 m²/g

t-Plot External Surface Area: 0.2919 m²/g

BJH Adsorption cumulative surface area of pores
 between 17.000 Å and 3000.000 Å diameter: 0.2629 m²/g

BJH Desorption cumulative surface area of pores
 between 17.000 Å and 3000.000 Å diameter: 0.3851 m²/g

Pore Volume

Single point adsorption total pore volume of pores
 less than 1222.6311 Å at p/p^{*} = 0.983908195: 0.000911 cm³/g

t-Plot micropore volume: -0.000004 cm³/g

BJH Adsorption cumulative volume of pores
 between 17.000 Å and 3000.000 Å diameter: 0.000879 cm³/g

BJH Desorption cumulative volume of pores
 between 17.000 Å and 3000.000 Å diameter: 0.000478 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 128.5417 Å

BJH Adsorption average pore diameter (4V/A): 133.826 Å

BJH Desorption average pore diameter (4V/A): 49.651 Å

Horvath-Kawazoe

Maximum pore volume at p/p^{*} = 0.983908195: 0.000911 cm³/g

Median pore width: 500.6344 Å

Dubinin-Radushkevich

Micropore surface area: 0.0000 m²/g

Monolayer capacity: 0.000000 cm³/g

Dubinin-Astakhov

MP-Method

Cumulative surface area of pores between
 18.4619 Å and 18.4619 Å hydraulic radius: 0.0000 m²/g

Cumulative pore volume of pores between
 18.4619 Å and 18.4619 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.2 N₂ adsorption isotherms (as referenced to in Section 3.2.1) for the HV sample size fraction 0.5–1 mm.

Summary Report

Surface Area

Single point surface area at p/p^{*} = 0.306693968: 0.2258 m²/g

BET Surface Area: 0.2271 m²/g

t-Plot Micropore Area: 0.0131 m²/g

t-Plot External Surface Area: 0.2139 m²/g

BJH Adsorption cumulative surface area of pores
 between 17.000 Å and 3000.000 Å diameter: 0.2087 m²/g

BJH Desorption cumulative surface area of pores
 between 17.000 Å and 3000.000 Å diameter: 0.3360 m²/g

Pore Volume

Single point adsorption total pore volume of pores
 less than 1362.2067 Å at p/p^{*} = 0.985584972: 0.000773 cm³/g

t-Plot micropore volume: 0.000007 cm³/g

BJH Adsorption cumulative volume of pores
 between 17.000 Å and 3000.000 Å diameter: 0.000750 cm³/g

BJH Desorption cumulative volume of pores
 between 17.000 Å and 3000.000 Å diameter: 0.000416 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 136.1775 Å

BJH Adsorption average pore diameter (4V/A): 143.821 Å

BJH Desorption average pore diameter (4V/A): 49.480 Å

Horvath-Kawazoe

Maximum pore volume at p/p^{*} = 0.985584972: 0.000773 cm³/g

Median pore width: 530.4943 Å

Dubinin-Astakhov

Micropore surface area: 0.2415 m²/g

Limiting micropore volume: 0.000119 cm³/g

MP-Method

Cumulative surface area of pores between
 18.6305 Å and 18.6305 Å hydraulic radius: 0.0000 m²/g

Cumulative pore volume of pores between
 18.6305 Å and 18.6305 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.3 N₂ adsorption isotherms (as referenced to in Section 3.2.1) for the HV sample size fraction 0.5–1 mm (duplicate)

Summary Report

Surface Area

Single point surface area at $p/p^\circ = 0.306404651$: $0.1960 \text{ m}^2/\text{g}$

BET Surface Area: $0.2047 \text{ m}^2/\text{g}$

t-Plot External Surface Area: $0.2319 \text{ m}^2/\text{g}$

BJH Adsorption cumulative surface area of pores between 17.000 \AA and 3000.000 \AA diameter: $0.2184 \text{ m}^2/\text{g}$

BJH Desorption cumulative surface area of pores between 17.000 \AA and 3000.000 \AA diameter: $0.3044 \text{ m}^2/\text{g}$

Pore Volume

Single point adsorption total pore volume of pores less than 1314.0579 \AA at $p/p^\circ = 0.985047321$: $0.000730 \text{ cm}^3/\text{g}$

t-Plot micropore volume: $-0.000017 \text{ cm}^3/\text{g}$

BJH Adsorption cumulative volume of pores between 17.000 \AA and 3000.000 \AA diameter: $0.000713 \text{ cm}^3/\text{g}$

BJH Desorption cumulative volume of pores between 17.000 \AA and 3000.000 \AA diameter: $0.000417 \text{ cm}^3/\text{g}$

Pore Size

Adsorption average pore width (4V/A by BET): 142.6879 \AA

BJH Adsorption average pore diameter (4V/A): 130.535 \AA

BJH Desorption average pore diameter (4V/A): 54.736 \AA

Horvath-Kawazoe

Maximum pore volume at $p/p^\circ = 0.985047321$: $0.000730 \text{ cm}^3/\text{g}$

Median pore width: 502.5869 \AA

Dubinin-Radushkevich

Micropore surface area: $0.0000 \text{ m}^2/\text{g}$

Monolayer capacity: $0.000000 \text{ cm}^3/\text{g}$

Dubinin-Astakhov

Micropore surface area: $0.1927 \text{ m}^2/\text{g}$

Limiting micropore volume: $0.000104 \text{ cm}^3/\text{g}$

Summary Report

Surface Area

Single point surface area at p/p⁰ = 0.306493757: 0.1889 m²/g

BET Surface Area: 0.1840 m²/g

t-Plot Micropore Area: 0.0673 m²/g

t-Plot External Surface Area: 0.1167 m²/g

BJH Adsorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.1360 m²/g

BJH Desorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.2716 m²/g

Pore Volume

Single point adsorption total pore volume of pores less than 1302.8106 Å at p/p⁰ = 0.984915925: 0.000648 cm³/g

t-Plot micropore volume: 0.000037 cm³/g

BJH Adsorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000622 cm³/g

BJH Desorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000378 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 140.9215 Å

BJH Adsorption average pore diameter (4V/A): 182.944 Å

BJH Desorption average pore diameter (4V/A): 55.630 Å

Horvath-Kawazoe

Maximum pore volume at p/p⁰ = 0.984915925: 0.000648 cm³/g

Median pore width: 558.1430 Å

Dubinin-Radushkevich

Micropore surface area: 0.0000 m²/g

Monolayer capacity: 0.000000 cm³/g

Dubinin-Astakhov

Micropore surface area: 0.2289 m²/g

Limiting micropore volume: 0.000108 cm³/g

MP-Method

Cumulative surface area of pores between 18.5627 Å and 18.5627 Å hydraulic radius: 0.0000 m²/g

Cumulative pore volume of pores between 18.5627 Å and 18.5627 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.5 N₂ adsorption isotherms (as referenced to in Section 3.2.1) for the HV sample size fraction 2–3 mm

Summary Report

Surface Area

Single point surface area at p/p^{*} = 0.306082984: 0.2306 m²/g

BET Surface Area: 0.2325 m²/g

t-Plot Micropore Area: 0.0090 m²/g

t-Plot External Surface Area: 0.2235 m²/g

BJH Adsorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.2099 m²/g

BJH Desorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.3402 m²/g

Pore Volume

Single point adsorption total pore volume of pores less than 1287.0712 Å at p/p^{*} = 0.984728143: 0.000724 cm³/g

t-Plot micropore volume: 0.000005 cm³/g

BJH Adsorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000699 cm³/g

BJH Desorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000446 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 124.6003 Å

BJH Adsorption average pore diameter (4V/A): 133.209 Å

BJH Desorption average pore diameter (4V/A): 52.474 Å

Horvath-Kawazoe
 Maximum pore volume at p/p^{*} = 0.984728143: 0.000724 cm³/g

Median pore width: 499.3694 Å

Dubinin-Radushkevich
 Micropore surface area: 0.0000 m²/g

Monolayer capacity: 0.000000 cm³/g

Dubinin-Astakhov

Micropore surface area: 0.2413 m²/g

Limiting micropore volume: 0.000119 cm³/g

MP-Method

Cumulative surface area of pores between 18.5438 Å and 18.5438 Å hydraulic radius: 0.0000 m²/g

Cumulative pore volume of pores between 18.5438 Å and 18.5438 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.6 N₂ adsorption isotherms (as referenced to in Section 3.2.1) for the M sample size fraction 0.25–0.5 mm

Summary Report

Surface Area

Single point surface area at p/p^{*} = 0.306243137: 0.3296 m²/g
 BET Surface Area: 0.3369 m²/g

t-Plot External Surface Area: 0.3645 m²/g

BJH Adsorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.3092 m²/g

BJH Desorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.4294 m²/g

Pore Volume

Single point adsorption total pore volume of pores less than 1235.3483 Å at p/p^{*} = 0.984076880: 0.000966 cm³/g
 t-Plot micropore volume: -0.000014 cm³/g

BJH Adsorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000924 cm³/g

BJH Desorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000514 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 114.6636 Å
 BJH Adsorption average pore diameter (4V/A): 119.546 Å
 BJH Desorption average pore diameter (4V/A): 47.848 Å

Horvath-Kawazoe

Maximum pore volume at p/p^{*} = 0.984076880: 0.000966 cm³/g
 Median pore width: 456.5032 Å

Dubinin-Radushkevich

Micropore surface area: 0.0000 m²/g
 Monolayer capacity: 0.000000 cm³/g

Dubinin-Astakhov

Micropore surface area: 0.3307 m²/g
 Limiting micropore volume: 0.000173 cm³/g

Dubinin-Astakhov

MP-Method

Cumulative surface area of pores between 18.4787 Å and 18.4787 Å hydraulic radius: 0.0000 m²/g

Cumulative pore volume of pores between 18.4787 Å and 18.4787 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.7 N₂ adsorption isotherms (as referenced to in Section 3.2.1) for the M sample size fraction 0.5–1 mm

Summary Report

Surface Area

Single point surface area at p/p^{*} = 0.306216622: 0.1905 m²/g

BET Surface Area: 0.1979 m²/g

t-Plot External Surface Area: 0.2323 m²/g

BJH Adsorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.2022 m²/g

BJH Desorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.2896 m²/g

Pore Volume

Single point adsorption total pore volume of pores less than 1337.1795 Å at p/p^{*} = 0.985310403: 0.000662 cm³/g

t-Plot micropore volume: -0.000020 cm³/g

BJH Adsorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000644 cm³/g

BJH Desorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000366 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 133.7969 Å

BJH Adsorption average pore diameter (4V/A): 127.409 Å

BJH Desorption average pore diameter (4V/A): 50.527 Å

Horvath-Kawazoe

Maximum pore volume at p/p^{*} = 0.985310403: 0.000662 cm³/g

Median pore width: 514.5350 Å

Dubinin-Radushkevich

Micropore surface area: 0.0000 m²/g

Monolayer capacity: 0.000000 cm³/g

Dubinin-Astakhov

MP-Method

Cumulative surface area of pores between 18.6026 Å and 18.6026 Å hydraulic radius: 0.0000 m²/g

Cumulative pore volume of pores between 18.6026 Å and 18.6026 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.8 N₂ adsorption isotherms (as referenced to in Section 3.2.1) for the M sample size fraction 0.5–1 mm (duplicate)

Summary Report

Surface Area

Single point surface area at p/p° = 0.306452934: 0.1912 m²/g

BET Surface Area: 0.1949 m²/g

t-Plot External Surface Area: 0.2070 m²/g

BJH Adsorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.1828 m²/g

BJH Desorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.2713 m²/g

Pore Volume

Single point adsorption total pore volume of pores less than 1425.8429 Å at p/p° = 0.986239149: 0.000636 cm³/g

t-Plot micropore volume: -0.000006 cm³/g

BJH Adsorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000612 cm³/g

BJH Desorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000355 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 130.4547 Å

BJH Adsorption average pore diameter (4V/A): 133.845 Å

BJH Desorption average pore diameter (4V/A): 52.315 Å

Horvath-Kawazoe

Maximum pore volume at p/p° = 0.986239149: 0.000636 cm³/g

Median pore width: 510.5666 Å

Dubinin-Radushkevich

Micropore surface area: 0.0000 m²/g

Monolayer capacity: 0.000000 cm³/g

Dubinin-Astakhov

Micropore surface area: 0.1951 m²/g

Limiting micropore volume: 0.000103 cm³/g

Horvath-Kawazoe Report

Slit Pore Geometry (Original H-K)

Maximum Pore Volume: 0.000642 cm³/g
 at Relative Pressure: 0.985459028
 Median Pore Width: 497.903 Å
 Relative Pressure Range: 1.137e-02 to 9.855e-01

Diameter of Adsorptive Molecule: 3.000 Å
 Diameter of Adsorptive at Zero Interaction Energy: 2.574 Å
 Diameter of Sample Atom: 3.040 Å
 Diameter of Sample Atom at Zero Interaction Energy: 2.609 Å
 Interaction Parameter: 3.49e-43 erg·cm⁴

Density Conversion Factor: 0.0015468

Summary Report

Surface Area

Single point surface area at p/p⁰ = 0.306382392: 0.2133 m²/g

BET Surface Area: 0.2167 m²/g

t-Plot External Surface Area: 0.2233 m²/g

BJH Adsorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.1956 m²/g

BJH Desorption cumulative surface area of pores between 17.000 Å and 3000.000 Å diameter: 0.3062 m²/g

Pore Volume

Single point adsorption total pore volume of pores less than 1350.6100 Å at p/p⁰ = 0.985459028: 0.000642 cm³/g

t-Plot micropore volume: -0.000003 cm³/g

BJH Adsorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000616 cm³/g

BJH Desorption cumulative volume of pores between 17.000 Å and 3000.000 Å diameter: 0.000377 cm³/g

Pore Size

Adsorption average pore width (4V/A by BET): 118.4574 Å

BJH Adsorption average pore diameter (4V/A): 126.012 Å

BJH Desorption average pore diameter (4V/A): 49.201 Å

Horvath-Kawazoe

Maximum pore volume at p/p⁰ = 0.985459028: 0.000642 cm³/g

Median pore width: 497.9027 Å

Dubinin-Radushkevich

Micropore surface area: 0.0000 m²/g

Monolayer capacity: 0.000000 cm³/g

Dubinin-Astakhov

MP-Method

Cumulative surface area of pores between 18.6177 Å and 18.6177 Å hydraulic radius: 0.0000 m²/g

Cumulative pore volume of pores between 18.6177 Å and 18.6177 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.10 N₂ adsorption isotherms (as referenced to in Section 3.2.1) for the M sample size fraction 2–3 mm

 18.7550 Å and 18.7550 Å hydraulic radius: 0.000000 cm³/g

Average pore hydraulic radius (V/A): 0.0000 Å

A2.11 Pore size distributions (PSD) according to the density functional theory (DFT) (as referenced to in Section 3.2.2) for the HV sample size fraction 0.25–0.5 mm
